## **SECTION I Membrane Applications in Chemical and Pharmaceutical Industries and in Conservation of Natural Resources**

<b>Chapter 1</b> Membrane Applications in Chemical and Pharmaceutical Industries and in Conservation of Natural Resources: Introduction.....	3
<i>Ana Maria Sastre, Anil Kumar Pabby, and Syed S.H. Rizvi</i>	
<b>Chapter 2</b> Application of Membrane Contactors as Mass Transfer Devices.....	7
<i>A. Sengupta and R.A. Pittman</i>	
<b>Chapter 3</b> Membrane Chromatography .....	25
<i>M.E. Avramescu, Z. Borneman, and M. Wessling</i>	
<b>Chapter 4</b> Membranes in Gas Separation.....	65
<i>May-Britt Hägg</i>	
<b>Chapter 5</b> Pervaporation: Theory, Practice, and Applications in the Chemical and Allied Industries.....	107
<i>Vishwas G. Pangarkar and Sangita Pal</i>	
<b>Chapter 6</b> Current Status and Prospects for Ceramic Membrane Applications.....	139
<i>Christian Guizard and Pierre Amblard</i>	
<b>Chapter 7</b> Membrane Technologies and Supercritical Fluids: Recent Advances .....	181
<i>D. Paolucci-Jeanjean, G.M. Rios, and S. Sarrade</i>	
<b>Chapter 8</b> Techniques to Enhance Performance of Membrane Processes .....	193
<i>A.G. Fane and S. Chang</i>	
<b>Chapter 9</b> Separation and Removal of Hydrocarbons Using Polymer Membranes .....	233
<i>S.I. Semenova</i>	
<b>Chapter 10</b> Zeolite Membranes: Synthesis, Characterization, Important Applications, and Recent Advances .....	269
<i>M. Arruebo, R. Mallada, and M.P. Pina</i>	

<b>Chapter 11</b>	Membrane Fouling: Recent Strategies and Methodologies for Its Minimization.....	325
	<i>Matheus F.A. Goosen, S.S. Sablani, and R. Roque-Malherbe</i>	
<b>Chapter 12</b>	Membrane Extraction in Preconcentration, Sampling, and Trace Analysis.....	345
	<i>Jan Åke Jönsson</i>	
<b>Chapter 13</b>	Hybrid Liquid Membrane Processes with Organic Water-Immiscible Carriers (OHLM): Application in Chemical and Biochemical Separations .....	371
	<i>Vladimir S. Kislik</i>	
<b>Chapter 14</b>	Advancements in Membrane Processes for Pharmaceutical Applications.....	409
	<i>Ralf Kuriyel, Masatake Fushijima, and Gary W. Jung</i>	
<b>Chapter 15</b>	Membranes in Drug Delivery .....	427
	<i>Mario Grassi</i>	
<b>Chapter 16</b>	Bio-Responsive Hydrogel Membranes.....	473
	<i>John Hubble and Rongsheng Zhang</i>	

## **SECTION II Membrane Applications in Biotechnology, Food Processing, Life Sciences, and Energy Conversion**

<b>Chapter 17</b>	Membrane Applications in Biotechnology, Food Processing, Life Sciences, and Energy Conversion: Introduction .....	495
	<i>Syed S.H. Rizvi</i>	
<b>Chapter 18</b>	Ultrafiltration-Based Protein Bioseparation.....	497
	<i>Raja Ghosh</i>	
<b>Chapter 19</b>	Membrane Distillation in Food Processing .....	513
	<i>Sanjay Nene, Ganapathi Patil, and K.S.M.S. Raghavarao</i>	
<b>Chapter 20</b>	Applications of Membrane Separation in the Brewing Industry .....	553
	<i>Carmen I. Moraru and Ernst Ulrich Schrader</i>	
<b>Chapter 21</b>	Developments of Bipolar Membrane Technology in Food and Bio-Industries.....	581
	<i>Gerald Pourcelly and Laurent Bazinet</i>	
<b>Chapter 22</b>	Applications of Membrane Technology in the Dairy Industry .....	635
	<i>Philipina A. Marcelo and Syed S.H. Rizvi</i>	
<b>Chapter 23</b>	Microporous Membrane Blood Oxygenators .....	671
	<i>S.R. Wickramasinghe and B. Han</i>	

<b>Chapter 24</b>	Transporting and Separating Molecules Using Tailored Nanotube Membranes .....	693
	<i>Punit Kohli and Charles R. Martin</i>	
<b>Chapter 25</b>	Use of Emulsion Liquid Membrane Systems in Chemical and Biotechnological Separations .....	709
	<i>Jilska M. Perera and Geoff W. Stevens</i>	
<b>Chapter 26</b>	Membrane Electroporation and Emerging Biomedical Applications.....	741
	<i>K.P. Mishra</i>	
<b>Chapter 27</b>	Proton-Conducting Membranes for Fuel Cells.....	759
	<i>Vineet Rao, K. Andreas Friedrich, and Ulrich Stimming</i>	

### **SECTION III Membrane Applications in Industrial Waste Management (Including Nuclear), Environmental Engineering, and Future Trends in Membrane Science**

<b>Chapter 28</b>	Membrane Applications in Industrial Waste Management (Including Nuclear), Environmental Engineering, and Future Trends in Membrane Science: Introduction .....	823
	<i>Ana Maria Sastre and Anil Kumar Pabby</i>	
<b>Chapter 29</b>	Treatment of Radioactive Effluents: Introduction, Fundamentals, and Scope of Different Membrane Processes .....	827
	<i>B.M. Misra and V. Ramachandhran</i>	
<b>Chapter 30</b>	Radioactive Waste Processing: Advancement in Pressure-Driven Processes and Current World Scenario.....	843
	<i>Grazyna Zakrzewska-Trznadel</i>	
<b>Chapter 31</b>	Liquid Membrane-Based Separations of Actinides.....	883
	<i>P.K. Mohapatra and V.K. Manchanda</i>	
<b>Chapter 32</b>	Reverse Osmosis-Based Treatment of Radioactive Liquid Wastes Generated in Hospital Facility and in Steel Industry: Case Studies .....	919
	<i>M. Sancho, J.M. Arnal, G. Verdú, and J. Lora</i>	
<b>Chapter 33</b>	Evaluation of Membrane-Based Processing of Radioactive Nuclear Plant Waste: Case Studies .....	933
	<i>Anil Kumar Pabby, S.K. Gupta, S.R. Sawant, N.S. Rathore, P. Janardan, R.D. Changrani, and P.K. Dey</i>	
<b>Chapter 34</b>	Application of Donnan Membrane Process for Recovery of Coagulants from Water Treatment Residuals .....	945
	<i>Prakhar Prakash and Arup K. SenGupta</i>

# Foreword

During the middle of the last century, when the first synthetic membrane with tailor-made separation properties became available, a multitude of technically and commercially interesting applications were identified. Today, 50 years later, membranes and membrane processes have indeed become valuable tools for the separation of molecular mixtures. They are the key components in artificial organs and in devices for the controlled release of active agents, or in energy conversion and storage systems. Seawater and brackish water desalination using reverse osmosis and electrodialysis are energy efficient and highly economic processes for large-scale production of potable water. Micro- and ultrafiltration are used for the production of high-quality industrial water and for the treatment of industrial effluents. Blood detoxification by hemodialysis and hemofiltration improves the quality of life for more than 1.3 million people suffering from acute and chronic renal failure. Membrane processes have found a multitude of applications in chemical and pharmaceutical industries as well as in food processing and biotechnology. They are used on a large scale in gas separation and as tools in analytical laboratories. Today's membrane-based industry is serving a rapidly growing multibillion euro market with a large number of products and processes. The development of membranes with improved properties will most likely increase the importance of membranes and membrane processes in a growing number of applications for the sustainable growth of modern industrial societies.

The term "membrane" refers not to a single item, but covers a large variety of structures and materials with very different properties. The same is true for membrane processes, which can be very different in the way they function. However, all membranes and membrane processes have one feature in common, i.e., they can perform the separation of certain molecular mixtures effectively and economically at ambient temperature, and without any toxic or harmful reaction by-products.

In the early days of membrane science and technology, research was mainly concentrated on elucidating the membrane mass transport mechanism and on developing membrane structures with specific mass transport properties. The fundamentals of most membrane processes and membrane preparation procedures are described in great detail in a large number of publications in various scientific journals and in several excellent textbooks. However, the application of membranes and membrane processes is much less comprehensively covered in today's literature. Only a relatively small number of applications of membrane processes such as reverse osmosis, micro- and ultrafiltration, and gas separation and pervaporation are treated in textbooks and reference books. A large number of interesting membrane applications in the food and drug industry, in chemical and electrochemical synthesis, and in artificial organs are often not adequately treated in the membrane-related literature, but are published in journals specific for certain industries, which are outside of the interest of many membrane scientists. Furthermore, application-oriented membrane studies that are often carried out in industrial enterprises are described only as patents, or are not published at all. Therefore, it is difficult to obtain a reasonably complete overview of the very large and heterogeneous field of membrane applications without reading a number of very different journals and patents where most of the publications are not really membrane related.

The aim of *Handbook of Membrane Separations: Chemical, Pharmaceutical, Food, and Biotechnological Applications* is to fill the gap in the presently available membrane literature by providing a comprehensive discussion of membrane applications in the chemical, food, and pharmaceutical industries, in biotechnology, and in the treatment of toxic industrial effluents. The applications of membranes in different areas are described by scientists and engineers who not only are experts in membrane science and technology but also have extensive experience in the specific field of membrane application. This book is not competitive, but rather complementary to other textbooks and handbooks on membrane science and technology presently available in the market. It provides enough background information on the various membrane components and processes to evaluate their potential applications without a detailed treatment of the fundamental aspects of membrane mass transport theories and membrane structure development. The book should, therefore, be of great value to scientists and engineers who are not necessarily membrane experts but are interested in using membrane processes in solving specific separation and mass transport problems. It is equally suited for the newcomers in the field of membrane science as for engineers and scientists, who do have basic knowledge in membrane technology but are interested in obtaining more information on specific present and potential future membrane applications. It also provides an excellent base for courses and lectures in postgraduate education.

# Preface

During the past two decades, membrane technology has grown into an accepted unit operation for a wide variety of separations in industrial processes and environmental applications. Tighter environmental legislation calls for equipment that is able to deal with the removal of components across a wide range of concentration levels and that offers considerable flexibility and efficiency. Membrane technology first became important during the 1960s and 1970s in water treatment and in processes such as reverse osmosis, ultrafiltration, dialysis, electrodialysis, and microfiltration. During the 1980s, membrane technology began to be applied on a large scale in the field of gas purification. The successful introduction of membrane technology in these fields was mainly the result of the development of reliable and selective polymeric membranes.

There are a number of reference publications in the field of membrane technology, such as handbooks, monographs, and compendia of conference and workshop proceedings. The relative abundance of such works begs the questions, “Why another?” and “How will this one be different?” These questions are probably best answered by considering what the *Handbook of Membrane Separations: Chemical, Pharmaceutical, Food, and Biotechnological Applications* has to offer. The handbook covers the full spectrum of membrane technology and discusses its advancement and applications in a series of chapters written by experts, prominent researchers, and professionals from all over the world.

The handbook is divided into three main sections: The first section deals with membrane applications in chemical and pharmaceutical industries, and in conservation of natural resources; the second section covers membrane applications in biotechnology, food processing, life sciences, and energy conversion. Finally, the third section deals with membrane applications in industrial waste management (including nuclear), environmental engineering, and future trends in membrane science. Each section is divided into chapters that deal with the subject matter in depth and focus on cutting-edge advancements in the field. Several authors were commissioned to write the chapters under the supervision of the editors, and each chapter was peer-reviewed for content and style before it was accepted for publication. The aim was to maintain the perspective of a practical handbook rather than merely a collection of review chapters.

The editors would like to acknowledge the contributions of a number of authors and institutions that have played a major role in drafting the handbook from conception to publication. The handbook would not have been possible without their input. These contributors are leading experts in their fields and bring a great wealth of experience to this book. The editors would also like to acknowledge the efforts of the reviewers who devoted their valuable time to revising the chapters before the deadlines and suggested improvements to maintain the high standard of the handbook. Finally, we would like to acknowledge the support of our home institutions at every stage in the handbook’s conception: the Bhabha Atomic Research Centre, Mumbai, India; Cornell University, Ithaca, New York; and the Universitat Politècnica de Catalunya, Barcelona, Spain.

# Editors

**Anil Kumar Pabby** is affiliated with one of the pioneering research centers of India, the Bhabha Atomic Research Centre (Department of Atomic Energy), Tarapur, Mumbai, Maharashtra. He received his PhD from the University of Mumbai and subsequently completed his postdoctoral research at the Universitat Politècnica de Catalunya, Barcelona, Spain. Dr. Pabby has more than 150 publications to his credit including 4 book chapters and a patent on nondispersive membrane technology. He was invited to join the team of associate editors at the *Journal of Radioanalytical and Nuclear Chemistry* during 2002–2005. He has also served as consultant to the International Atomic Energy Agency (IAEA) for developing a technical document on the application of membrane technologies for liquid radioactive waste processing. Dr. Pabby has been a regular reviewer for several national and international journals and also serves on the editorial board of various journals. His research interest includes pressure-driven membrane processes, nondispersive membrane techniques, extraction chromatography, solvent extraction, and macrocyclic crown compounds. In 2003,

Dr. Pabby was elected fellow of the Maharashtra Academy of Sciences (FMASc) for his contribution to membrane science and technology. In 2005, he received the prestigious Tarun Datta Memorial Award (instituted by Indian Association for Nuclear Chemists and Allied Scientists) for his outstanding contribution to nuclear chemistry and radiochemistry.

**Syed S.H. Rizvi** is an international professor of food process engineering and has served as director of graduate studies at the Cornell Institute of Food Science, Cornell University, Ithaca, New York. He has a PhD from Ohio State University, an MEng (chemical engineering) from the University of Toronto, and a BTech from Panjab University, India. Dr. Rizvi teaches courses devoted to engineering and processing aspects of food science and related biomaterials. His laboratory is engaged in research on experimental and theoretical aspects of bioseparation processes using supercritical fluids and membranes, high-pressure extrusion with supercritical carbon dioxide, physical and engineering properties of biomaterials, and novel food processing technologies. An invention of Cornell researchers, and subsequently patented, supercritical fluid extrusion offers several advantages over the conventional high-shear cooking extrusion and is being used to investigate the dynamics of the process and the mechanics of the microcellular extrudates generated for both food and nonfood applications. A major long-term goal is to

develop new and improved unit operations for value-added processing of food and biomaterials. Derivative goals include new techniques for measurement and control of processes and properties for industrial applications. Dr. Rizvi has published more than 140 technical papers, coauthored/edited 6 books, served on the editorial board of several journals, and holds 7 patents.

**Ana Maria Sastre** is a professor of chemical engineering at the Universitat Politècnica de Catalunya (Barcelona, Spain), where she has been teaching chemistry for more than 28 years. She received her PhD from the Autonomous University of Barcelona in 1982 and has been working for many years in the field of solvent extraction, solvent impregnated resins, and membrane technology.

She was a visiting fellow at the Department of Inorganic Chemistry, the Royal Institute of Technology, Sweden, during 1980–1981 and carried out postdoctoral research from October 1986 to April 1987 at Laboratoire de Chimie Minerale, Ecole Europeenne des Hautes Etudes des Industries Chimiques de Strasbourg, France. Professor Sastre has more than 190 journal publications and more than 80 papers in international conferences. Dr. Sastre also holds four patent applications, guided 11 PhD and 16 master thesis students, and is a

reviewer of many international journals. In 2003, she was awarded the Narcis Monturiol medal for scientific and technological merits, given by the Generalitat de Catalunya for her outstanding contribution to science and technology.

Professor Sastre was the head of the chemical engineering department from 1999 to 2005 and is presently vice rector (vice chancellor) for academic policy at the Universitat Politècnica de Catalunya.

## CONTENTS

References .....	5
------------------	---

In the last 40 years, membranes have developed from a research topic to a mature industrial separation technology. This increase in the use of membrane technology is driven by spectacular advances in membrane development, the wider acceptance of the technology in preference to conventional separation processes, increased environmental awareness and, most importantly, strict environmental regulations and legislation. Various membrane processes are currently applied in the chemical (including petrochemicals), pharmaceutical, and food and beverage industries. Particularly, strong development and growth of membrane technology can be observed in the purification of wastewater and the production of drinking water.

This statement summarizes the discussions at a conference on the “Exploration of the potential of membrane technology for sustainable decentralized sanitation” held in Italy (at Villa Serbelloni, Bellagio) on 23–26 April 2003 [1].\*

Due to plummeting costs and dramatically improving performance, water-treatment applications based on membranes are blossoming. In particular, membrane bioreactors (MBRs) are today robust, simple to operate, and ever more affordable. They take up little space, need modest technical support, and can remove many contaminants in one step. These advantages make it practical, for the first time, to protect public health and safely reuse water for non-potable uses. Membranes can also be a component of a multi-barrier approach to supplement potable water resources. Finally, decentralization, which overcomes some of the sustainability limits of centralized systems, becomes more feasible with membrane treatment. Because membrane processes make sanitation, reuse, and decentralization possible, water sustainability can become an achievable goal for the developed and developing worlds.

A membrane can essentially be defined as a barrier that separates two phases and selectively restricts the transport of various chemicals. It can be homogenous or heterogeneous, symmetric or asymmetric in structure, solid or liquid, and can carry a positive or negative charge, or be neutral or bipolar. Transport across a membrane can take place by convection or by diffusion of individual molecules, or it can be induced by an electric field or concentration, pressure or temperature gradient. The membrane thickness can vary from as little as 100  $\mu\text{m}$  to several millimeters.

A membrane separation system separates an influent stream into two effluent streams known as the permeate and the concentrate. The permeate is the portion of the fluid that has passed through the semipermeable membrane, whereas the concentrate stream contains the constituents that have been rejected by the membrane.

The correct choice of membrane should be determined by the specific objective, such as the removal of particulates or dissolved solids, the reduction of hardness for the production of ultra pure water or the removal of specific gases/chemicals. The end use may also dictate the selection of membranes in industries such as potable water, effluent treatment, desalination, or water supply for electronic or pharmaceutical manufacturing.

Membrane technology covers various chemical technology disciplines, such as material science and technology, mass transport and process design. By manipulating material properties, membranes can be tailor-made for particular separation tasks

to be performed under specific separation conditions. Membranes are manufactured as flat sheets, capillaries, or in tubular shapes and are applied in various module configurations. The following membrane modules are commonly used for industrial applications: (a) the plate and frame module; (b) the spiral wound module; (c) the tubular membrane module; (d) the capillary membrane module; and (e) the hollow fiber membrane module.

Membrane separation processes have numerous industrial applications and provide the following advantages: They offer appreciable energy savings; they are environmentally benign; the technology is clean and easy to operate; they replace conventional processes like filtration, distillation, and ion exchange; they produce high-quality products; and they offer greater flexibility in system design. Pressure-driven processes such as ultrafiltration, nanofiltration, and microfiltration are already established and various applications have been commercialized in the fields of pharmaceutical and biotechnology. Recently, the development of a means of characterizing, controlling, and preventing membrane fouling has been proved vital. The development of tailored membranes, fouling prevention, and optimization of chemical cleaning will ensure a high level of membrane process performance. In the last five years, the development of new techniques for membrane characterization and the improvement of existing techniques have increased our knowledge of the mechanisms involved in membrane fouling. More advanced techniques, such as environmental scanning electron microscopy (ESEM), have been used to study membrane fouling during the microfiltration of high metal content solutions with aluminum oxide membranes [2]. This will provide not only useful insight into the fouling mechanism but also a better understanding of the factors that affect membrane fouling.

The combination of molecular separation with a chemical reaction, or membrane reactors, offers important new opportunities for improving the production efficiency in biotechnology and in the chemical industry. With regard to the future of biotechnology and pharmaceutical processes, the availability of new high-temperature-resistant membrane contactors offers an important tool for the design of alternate production systems appropriate for sustainable growth.

Membrane technology has widespread applications in chemical and pharmaceutical industries and its use in various other fields is increasing rapidly. It has established applications in areas such as hydrogen separation, the recovery of organic vapors from process gas streams, and the selective transport of organic solvents, and it is creating new possibilities for catalytic conversion in membrane reactors. It provides a unique solution for industrial waste treatment and for the controlled production of valuable chemicals. Since it deals with the smallest penetrants in the size spectrum, gas separation requires extremely precise discrimination of size and shape—often in the range of 0.2–0.3 Å—between permeated and rejected species. Such demands truly push the state of the art in materials science for these specific applications. In addition to polymeric media, ceramic, carbon, zeolite, and metal membranes are attractive options as they provide both precise separation and robustness. Vision and commitment are required to make the most of the large energy savings (and CO<sub>2</sub> emission reductions) offered by membranes when compared with traditional, thermally driven separations and energy conversion. The use of membranes for extraction in analytical chemistry has increased recently. The main aim is to selectively extract and enrich the compounds to be determined (analytes) from samples of varying chemical complexity. In contrast to many technical uses of membranes, in analytical applications it is essential to recover the extracted analytes as efficiently as possible so that they can be transferred to suitable analytical instruments for the final quantitative determination.

Similarly, membrane contactors have proved to be efficient contacting devices, due to their high area per unit volume that results in high mass transfer rates. They are not only compact but also eliminate several of the problems faced in conventional processes such as ion exchange, solvent extraction, and precipitation. Membrane contactor processes, in which phase contacting is performed or facilitated by the structure and shape of the porous membrane, provide new dimension to the growth of membrane science and technology and also satisfy the requirements for process intensification. In addition, membrane contactors represent a significant step forward from the initial success of blood oxygenators. Their integration with other membrane systems, including membrane reactors, could lead to the redesign of membrane-based integrated production lines.

This introductory section outlines several established applications of membranes in the chemical and pharmaceutical industries, reviews the membranes and membrane processes available in this field, and discusses the huge potential of these technologies. In addition, other important topic dealing with conservation of natural resources (zeolite membranes) is also presented in this section. Each chapter has been written by a leading international expert with extensive industrial experience in the field.

Chapter 1 (the current chapter) presents an overview of different membrane processes and a description of all of the chapters presented in Section I. Chapter 2 explains the potential of hollow fiber contactors in the field of chemical technology and how they have changed industrial preferences regarding contacting devices. This chapter gives an introduction to membrane contact technology, its principles of operation, and the benefits obtained from the use of membrane contactors. Important applications, new product development requirements, and future directions are also discussed. Chapter 3 deals with membrane chromatography. This chapter discusses the latest developments in membrane-based stationary phases (affinity membranes and mixed matrix membrane adsorbers) and monolithic separation media (organic and inorganic). It also provides information on new types of chromatographic support, focusing on membrane materials, properties, and preparation. Finally, it considers possible applications of chromatographic membranes in various process conditions. Chapter 4 focuses on the important aspects of membrane application in gas separation. It deals with the subject comprehensively, providing an

introduction and discussing transport mechanisms, different membrane materials for gas separation, module design, current and potential applications, and novel developments in this field. Chapter 5 presents developments in pervaporation (PV). It first gives a brief introduction to the theory of pervaporation and then discusses sorption thermodynamics in polymers, the solution diffusion model, the criteria for membrane polymer selection, and important applications of PV in different cases of aqueous and organic separation. Chapter 6 focuses on advances in the field of ceramic membranes, covering interesting applications in this area. Chapter 7 describes important developments in the fields of supercritical fluids and membrane technology. Chapter 8 presents the various methodologies or techniques for improving the membrane performance of microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. The aim is to present the techniques that attempt to minimize concentration polarization (and fouling) and allow the membrane to perform closer to its intrinsic capability. The methods range from the critical flux approach to the suite of hydrodynamic techniques and other potential strategies. Chapter 9 records important developments in the field of polymeric membranes for the separation and removal of hydrocarbons. It provides an introduction to the subject, discusses the background and physicochemical regularities of hydrocarbon permeation in membrane-based glassy and rubbery polymers, and lists some important applications. Chapter 10 describes some of the main characteristics of the use of zeolite membranes in separation applications. Zeolite membranes separate molecules based on the differences in their adsorption and diffusion properties. They are therefore suitable for separating gas and liquid phase mixtures by gas separation and pervaporation, respectively. This chapter reviews the basic mechanisms of gas separation and pervaporation through zeolite membranes and presents examples of industrial applications. Chapter 11 focuses on membrane fouling and the strategies used to reduce it relative to pressure-driven processes. This chapter highlights recent strategies for minimizing membrane fouling. In particular, it discusses the literature on fouling phenomena in reverse osmosis and ultrafiltration membrane systems, the analytical techniques employed to quantify fouling, preventive methods, and membrane cleaning strategies. Specific recommendations are also made on how scientists, engineers, and technical staff can help to improve the performance of these systems by minimizing membrane fouling phenomena. Chapter 12 describes membrane extraction and its use in preconcentration, sampling, and trace analysis. Chapter 13 presents applications of aqueous hybrid liquid membranes (AHLM) and organic hybrid liquid membranes (OHLM) in the separation of organic and metal species, respectively.

Chapter 14 provides an introduction to membrane applications in the pharmaceutical industry, its current status, and future potential in this very important area. Chapter 15 is devoted to membrane applications in the drug delivery field with emphasis on the mechanisms governing mass transport to modulate the release kinetics. Hydrogel membranes, as a derivative construct of hydrogels, have become increasingly attractive for precisely controlling the drug delivery rate via chemical sensing and triggering. Their current status, challenges, and opportunities are highlighted in Chapter 16.

## 2.1 INTRODUCTION

Membrane contactors as a type of membrane device have been known for quite a few years now [1–2]. They involve a unique class of membrane-based mass transfer and separation technologies, which have grown beyond academic curiosity and found commercial applications across various industries and markets. It has been found to be a cost-effective technology and is therefore used to supplant or replace other technologies that might or might not be based on membranes. In some situations, membrane contacting has emerged as an enabling technology that is filling some previously unmet commercial needs.

By the standard of business size, membrane contactor technology is currently a minor player compared to other much better-known membrane separation technologies such as reverse osmosis (RO), membrane filtration, membrane gas separation, diffusion dialysis, and electrodialysis. By its very nature, the membrane contactor does not function or compete with the other membrane devices, and the capability and functionality of contactors are significantly different from the other devices. But membrane contactor technology seems to have the potential to be applicable over a much wider array of industries. Use of membrane contactor devices in various forms is growing continuously. In many applications the contactor is not even called a contactor but is referred to by other names depending on the specific application it is deployed in. Examples include blood oxygenator (the earliest use of membrane contactor), gas transfer membrane, membrane degasifier, membrane deaerator, membrane distillation device, osmotic distillation device, membrane gas absorber, membrane extractor, and membrane humidifier.

## 2.2 SCOPE OF THIS CHAPTER

Considering the wide applications of membrane contactors and the evolving nature of this technology, it is difficult to cover every aspect in a monograph. The intent of this article is to first explain the technology and the principles of operation, with some remarks on the mass transfer process in membrane contactors. This is followed by description of various types of contacting possibilities and review of a wide sampling of literature on the technology to date. Design options of membrane

---

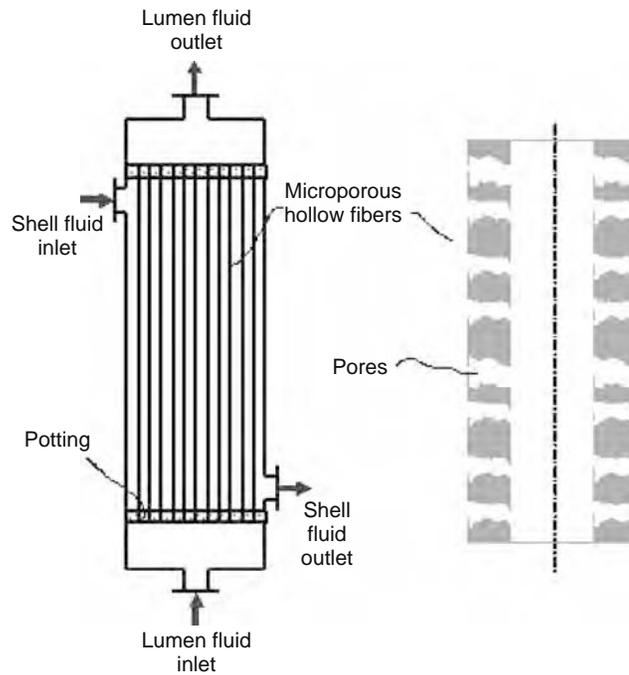

FIGURE 2.1 Microporous hollow fiber membrane in a membrane contactor.

contactors are then reviewed. Finally, some current and emerging commercial applications at different stages of development are discussed in detail.

### 2.3 DESCRIPTION OF MEMBRANE CONTACTOR

From outward appearance membrane contactors look similar to other membrane devices. However, functionally the membranes used in contactors are very different. They are mostly nonselective and microporous. Membrane contactors can be made out of flat sheet membranes and there are some commercial applications. Most common commercial membrane contactors are, however, made from small-diameter microporous hollow fiber (or capillary) membranes with fine pores (illustrated in Figure 2.1) that span the hollow fiber wall from the fiber inside surface to the fiber outside surface. The contactor shown as an example in Figure 2.1 resembles a tube-in-shell configuration with inlet/outlet ports for the shell side and tube side. The membrane is typically made up of hydrophobic materials such as Polypropylene, Polyethylene, PTFE, PFA, and PVDF.

The membrane in a contactor acts as a passive barrier and as a means of bringing two immiscible fluid phases (such as gas and liquid, or an aqueous liquid and an organic liquid, etc.) in contact with each other without dispersion. The phase interface is immobilized at the membrane pore surface, with the pore volume occupied by one of the two fluid phases that are in contact. Since it enables the phases to come in direct contact, the membrane contactor functions as a continuous-contact mass transfer device, such as a packed tower. However, there is no need to physically disperse one phase into the other, or to separate the phases after separation is completed. Several conventional chemical engineering separation processes that are based on mass exchange between phases (e.g., gas absorption, gas stripping, liquid-liquid extraction, etc.) can therefore be carried out in membrane contactors.

### 2.4 PRINCIPLE OF OPERATION

Principle of membrane contactor operation is based on the natural phenomenon of capillary force. When one side of a hydrophobic microporous membrane is brought in contact with water or an aqueous liquid, the membrane is not “wetted” by the liquid, i.e., the liquid is prevented from entering the pores, due to surface tension effect. The interface between a liquid and a solid substrate can be characterized by the parameter “contact angle” (Figure 2.2). The wettability of a solid surface by a liquid surface decreases as the contact angle increases. A contact angle of less than  $90^\circ$  implies that the liquid will tend to wet the substrate (hydrophilic), whereas if contact angle is greater than  $90^\circ$  the liquid will not tend to wet the surface (hydrophobic). Table 2.1 lists the contact angle values for few different materials in water at ambient temperature.

If a dry microporous hydrophobic hollow fiber membrane with air-filled pores was surrounded by water there would not be any penetration by water into the pores until the water pressure exceeds a certain critical breakthrough pressure. The magnitude

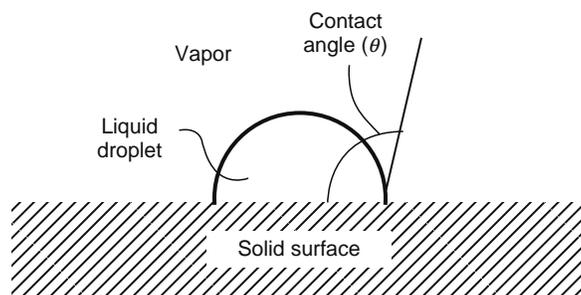

FIGURE 2.2 Representation of contact angle.

of this critical breakthrough pressure “differential” (water pressure minus air pressure)  $\Delta P_C$  has been mathematically derived, and is expressed [3] by the following equation that is often referred to as the Young–Laplace equation:

$$\Delta P_C = -\frac{4\lambda \cos \theta}{d} \quad (2.1)$$

where

$\lambda$  is the surface tension of water

$\theta$  is the contact angle for the system air–water–membrane in degrees

$d$  is the effective diameter of the membrane pore, assuming pores are circular in shape

For a hydrophobic porous material with contact angle greater than  $90^\circ$ , the  $\Delta P_C$  is  $>0$  and depends on the liquid surface tension and the membrane pore size. As an example, considering water–air–polypropylene system, one can calculate that for a dry membrane with a pore size of  $0.03 \mu\text{m}$  (30 nm) the critical entry pressure of water is more than 300 psi ( $>20$  bar).

Since the liquid phase does not enter the pores, a stable gas–liquid phase interface can be created and maintained (as illustrated in Figure 2.3) as long as the liquid phase pressure is higher than the gas phase pressure and the phase pressure differential  $\Delta P$  is between 0 and  $\Delta P_C$ . The pores remain air filled at this condition. The liquid and the gas phases could be flowing at different flow rates on either side of the membrane wall, but the phase interface remains stable all along the membrane. Thus, by proper control of pressures, the two immiscible phases come in constant contact without a need to disperse one into the other. This allows mass transfer or mass exchange between phases [4–5], such as gas absorption or gas stripping (desorption).

The same principle of operation as described above is applicable also to liquid–liquid extraction where an aqueous liquid and an organic liquid contact each other inside the contactor for extraction of a solute selectively from one phase to another [6–8]. The critical breakthrough pressure for liquid–liquid system could be calculated by Equation 2.1, except that the term  $\lambda$  would now be the interfacial tension between the two liquids. Further variation of membrane contacting technology is called gas membrane or gas–gap membrane where two different liquid phases flow on either side of the membrane, but the membrane pores remain gas filled [9–10]. In this situation two separate gas–liquid contact interfaces are supported on each side of a single membrane.

**TABLE 2.1**

## 2.5 BENEFITS OF MEMBRANE CONTACTOR TECHNOLOGY

Primary list of features and resulting benefits for the technology are shown in Table 2.2.

## 2.6 MASS TRANSFER PROCESS IN MEMBRANE CONTACTOR

In gas–liquid, liquid–liquid, or liquid–gas–liquid contactors there is no convective flow of any phase across the membrane. Mass transfer occurs only by diffusion across the immobilized phase in the pores. The direction of mass transfer of any molecular species depends on the concentration driving force maintained across the membrane for that species. The presence of the stationary phase in the membrane pore creates an extra diffusional mass transfer resistance. However, it can be shown that in many cases the membrane resistance is negligible, and that in most cases the high active mass transfer area created inside a membrane contactor more than compensates for any additional mass transfer resistance [4–5].

Mass transfer resistance in a continuous-contact separation device is the inverse of the mass transfer coefficient. In membrane contactors, the total resistance could be expressed as three resistances in series. These include the individual resistances in each flowing phase and the membrane resistance (Figure 2.4). For a liquid–gas contact system Equation 2.2 could be written for each diffusing species:

$$\frac{1}{d_{\text{OUT}}K_{\text{TOTAL}}} = \frac{1}{d_{\text{OUT}}k_{\text{SHELL}}} + \frac{1}{Hd_{\text{AVG}}k_{\text{M}}} + \frac{1}{Hd_{\text{IN}}k_{\text{TUBE}}} \quad (2.2)$$

where

$K$  is the overall coefficients

$k$  is the individual mass transfer coefficients

**TABLE 2.2**  
**Benefits of Membrane Contactor Technology**

Features	Benefits
High concentration of active phase contact area	Profile or footprint of membrane contactor systems are small; fit into existing building; no additional structure needed
Flow rates of phases in contact can be controlled independently	No physical limitations such as flooding or loading; contact area constant irrespective of phase flow rates; process more flexible
Modular in nature	Easier to add system capacity incrementally; can often be retrofitted into existing systems; easier scale-up
Mass transfer does not depend on gravity	Contactor can be mounted vertically or horizontally; will also work in microgravity; able to process two fluid phases of same densities
No need to disperse or coalesce phases	Eliminates extra steps; more efficient utilization of device volume
Can be operated with high fluid outlet pressures	Eliminates or reduces need for transfer pumps or booster pumps after contactor

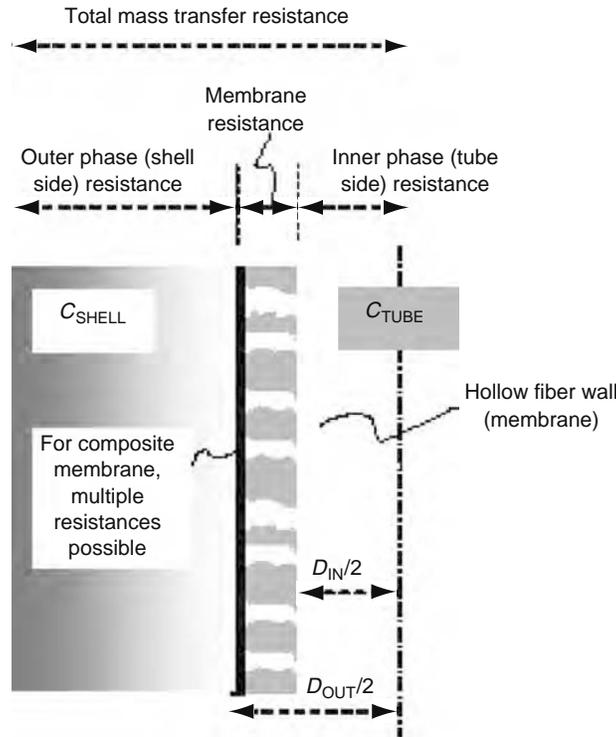

FIGURE 2.4 Mass transfer resistances in membrane contactor.

Each term on right side of Equation 2.2 represents an individual resistance as depicted in Figure 2.4. Hollow fiber diameters are  $d_{OUT}$  and  $d_{IN}$ . The term  $H$  is the Henry coefficient (liquid–gas equilibrium constant) for the species in question. In the case of liquid–liquid contact, the term  $H$  in Equation 2.2 should be replaced by  $m_D$ , the equilibrium distribution coefficient between tube side liquid and shell side liquid.

The membrane transfer coefficient  $k_M$  is a function of (1) the diffusion coefficient in the phase occupying membrane pores and (2) various membrane geometric parameters. Assuming pure Fickian diffusion in a symmetric microporous membrane,  $k_M$  can be shown as [5]

$$k_M = \frac{2D\varepsilon_M}{\tau_M(d_{OUT} - d_{IN})} \quad (2.3)$$

where

$D$  is diffusivity in the pore phase

$\varepsilon_M$  and  $\tau_M$  are membrane porosity and tortuosity factors, functions of the membrane morphology

In case of complex membrane morphology such as asymmetric or composite membranes, or when Fickian diffusion is not valid, evaluating  $k_M$  will be more complex. Individual mass transfer coefficients in Equation 2.2 depend on multiple factors such as temperature, pressure, flow rates, and diffusion coefficients and could often be estimated from empirical correlations available in literature [1,2,6].

The rate of mass transfer,  $R$ , for each species from shell side to tube side at any point inside the contactor is given as

$$R = K_{TOTAL} A [C_{SHELL} - C_{TUBE}] \quad (2.4)$$

where

$A$  is the membrane transfer area based on outside diameter of the hollow fiber

$C_{SHELL}$  and  $C_{TUBE}$  are bulk concentrations of the species in shell side and tube side, respectively

Strictly speaking Equations 2.2 and 2.4 are valid only locally within the contactor. The concentrations in each phase could change continuously inside the contactor. It is also possible for one of the mass transfer coefficients to change within the contactor. In such cases rate of mass transfer will be varying continually within the contactor, and the average overall mass transfer will be obtained by integrating over the entire contactor.

Useful simplifications are often made in Equation 2.2. We will use gas–liquid contact as an example, and assume gas-filled homogeneous membrane of high porosity, thin wall, and low tortuosity. Since diffusion in gas phase is generally of three orders of magnitude faster than in liquid phase, one can show that  $k_M$  and  $k_G$  are quite high in this case compared to  $k_L$ , and so the controlling resistance to mass transfer is in the liquid phase. This means  $K_{TOTAL}$  is essentially the same as  $k_L$ . If  $k_L$  is constant within the contactor the total mass transfer rate in Equation 2.4 can be approximated for the entire contactor as

$$R = k_L A_{TOTAL} \Delta C_{LOG-MEAN} \quad (2.5)$$

$\Delta C_{LOG-MEAN}$  is the log mean of the concentration differential ( $C_{SHELL} - C_{TUBE}$ ) from one end of the contactor to the other.

## 2.7 LITERATURE REVIEW ON MEMBRANE CONTACTOR APPLICATIONS

Over the years many research and development groups, both academic and industrial, have investigated membrane contactor technology and suggested or developed a wide range of possible applications. There is quite a spectrum of patent and published literature on this subject. Markets and industries that benefit from the development of this technology include medical, biotechnology, pharmaceutical, semiconductor and electronics, food and beverage, environmental, and other special process industries that are finding new uses. It is impossible to mention all the work done to date.

## 2.8 USE OF GAS–LIQUID OR LIQUID–GAS–LIQUID CONTACT

As mentioned earlier, membrane blood oxygenators probably would qualify as the earliest form of membrane contactors. Reference [11] is a good illustration of a hollow fiber device. However, most work on liquid–gas membrane contactor over the years has focused mainly on two categories: (1) separation, purification, and treatment of water or aqueous media and (2) absorption of gaseous species from air either for purification or for recovery, which will be discussed separately. Applications in multiple markets and industries have been investigated in each category.

An early example of a patent on membrane contactor for gas transfer is in Ref. [12]. Harvesting of oxygen dissolved in water and discharging of  $CO_2$  to the water is presented in Ref. [13]. A membrane device to separate gas bubbles from infusion fluids such as human-body fluids is claimed in Ref. [14]. A hollow fiber membrane device for removal of gas bubbles that dissolve gasses from fluids delivered into a patient during medical procedures is disclosed in Ref. [15]. Membrane contactors have also found application in dissolved gas control in bioreactors discussed in Refs. [16–17].

Application of membrane contactors for water degasification has been thoroughly investigated and reported in Refs. [18–21]. During the last few years this has been one of the most successful applications of membrane contactors on large commercial scale. Specifically, oxygen removal and gas transfer from ultrapure water for semiconductor industry have been discussed in Refs. [22–27]. Deaeration process for beverage water is discussed in Ref. [28]. Oxygen removal from boiler feed water as substitute for steam deaerator or oxygen scavenger is presented in Ref. [29]. Membrane contactors have also been used to carbonate water [30], to nitrogenate beer [31], to simultaneously nitrogenate and decarbonate beer, to control  $CO_2$  level in beer, and to control dissolved gas profile in beverages using mixed sweep gases of  $CO_2$  and  $N_2$  [32–33].

Removal of dissolved volatile organic compounds (VOC) from water in membrane contactors has been the subject of several investigations. VOC can be separated from water by applying a vacuum, the process is often termed vacuum membrane distillation [34–36]. Alternately, air can be used as a sweep gas to strip VOCs from water across the membrane [37]. Air stripping of water in packed or spray columns is a widely accepted process for ground water or process water treatment. If membrane contactors were used broadly for this purpose, the market potentials are certainly high. A variation of membrane air stripping process is discussed in Ref. [38] where the driving force for VOC stripping of water is established using methanotropic bacteria. Total organic carbon (TOC) reduction from ultrapure water during membrane degassing has been reported in Ref. [39]. Removal of tri-halo methane (THM) compounds, a chemical class of undesirable species, from ultrapure water has been discussed in Ref. [40]. Use of microporous membranes in combination with RO to separate dissolved gases from water is disclosed in Ref. [41]. Study on removal and recovery of volatile aroma compounds from water was presented in Ref. [42].

Adding oxygen or other beneficial gas species to water without forming gas bubbles is another application of membrane contactors. This subject has been discussed in Refs. [43–46]. Membranes in module form and hollow fibers in unconfined form have been investigated. Use of membrane contactors for supplying oxygen to a biofilm is claimed in Ref. [47]. A similar process where gaseous hydrogen is added to aqueous liquid without bubble formation is disclosed in Ref. [48]. The purpose for such a process would be to use dissolved hydrogen to biologically or catalytically remove oxygen, nitrite, or nitrate from water. Membrane contactors are also used to add trace quantity of  $CO_2$  into ultrapure water to control water resistivity and prevent formation of static electricity [49]. A more recent and significant application of membrane contactors is the addition of gaseous ozone to water for the purpose of disinfection and removal of organic contamination, such a process is disclosed in Ref. [50].

A number of applications of the previously termed gas membrane have also been studied over the years to remove or recover volatile species from water or other aqueous media. The primary drivers for these investigations are the intriguing and

creative possibilities of the gas membrane, which in effect combines two gas–liquid contact processes (stripping and absorption) within a single microporous membrane. Some of the early-published studies include recovery of bromine [51], cyanide [52], ammonia [53–55], and ethanol [56]. Applications of this technology for commercial purposes are in various stages of development [57].

Membrane processes termed as osmotic distillation or membrane distillation could be shown to be applications of membrane contactor technology also. Both of these processes are based on gas membranes. Osmotic distillation, sometimes called osmotic evaporation, involves transfer of water vapor across a gas-filled membrane, the process is driven by a difference in water vapor pressure maintained across the membrane [58–59] by separate aqueous liquids. Membrane distillation is a process where water vapor transfer is driven solely by a temperature difference across the gas-filled membrane [60–61]. Water evaporates from a hot aqueous phase and condenses on a cooler surface. This process may be useful in desalinating water or producing pure water if a good natural source of warm water is available, such as in a geothermal process.

As mentioned in Table 2.2, one unique feature of membrane contactors is the ability to operate without the aid of gravity. This, along with the advantage of smaller sizes for contactor systems, has led to the interest in possible use of this technology in microgravity and confined spaces such as spacesuits, manned spacecrafts, and space station. Primary applications are (1) separating gas and liquid phases in microgravity and (2) removal of unwanted gas species from liquids [62–64].

We now discuss the second category of applications that focus on treatment and conditioning of air or gas streams. This is done either (1) by capturing (absorbing) gaseous species from air or other gases into water or aqueous liquids or (2) by controlling the properties of air or gas phase by other means of heat and mass transfer across membrane in a contactor. The first detailed investigation of absorption of a gas species ( $\text{CO}_2$ ) in a liquid using a membrane contactor was discussed in detail in Refs. [4,5]. The mass transfer analysis in these early papers has been most influential for understanding the technology.

Absorption of various gases such as  $\text{CO}_2$ ,  $\text{SO}_2$ ,  $\text{NH}_3$ , and carbon monoxide in water using membrane contactors was studied by many other research groups and reported in Refs. [65–70]. Removal of  $\text{CO}_2$  as a greenhouse gas from air and bulk removal of  $\text{CO}_2$  from air in contactors using conventional absorbents have been reported in Refs. [71–73]. The topic of scrubbing  $\text{CO}_2$  from air for self-contained breathing systems using microporous membrane is discussed in Ref. [74]. Capturing  $\text{CO}_2$  from atmosphere using membrane contactors, as part of a hydrogen storage process, was suggested in Ref. [75]. Use of membrane contactors for recovery of VOCs from air was reported in Ref. [76]. A hollow fiber membrane bioreactor, for the purpose of destroying toxic compounds from air, is shown in Ref. [77].

Controlling temperature and humidity of process air or ambient air is another unique application of membrane contactors. Membranes are used to humidify or dehumidify air by bringing air in contact with water or a hygroscopic liquid. Mass transfer in such processes is very fast since mass transfer resistance in the liquid phase is negligible. Heat transfer and mass transfer are directly related to these processes, since latent heat of evaporation (or condensation) creates temperature profiles inside the contactor. Some of the references in Literature are shown in Refs. [78–79]. Application of such processes has been proposed for conditioning air in aircraft cabins [80], in buildings or vehicles [81], or in containers to store perishable goods [82].

## 2.9 USE OF LIQUID–LIQUID CONTACT

A historical perspective on aqueous–organic extraction using membrane contactor technology is available in Refs. [1,6,83]. The mechanism of phase interface immobilization was first explored in Ref. [84], while application of membrane solvent extraction for a commercial process was first explored in Ref. [85]. Two aspects of liquid–liquid contact in membrane contactors that are different from typical gas–liquid contact are (1) the membrane used could be hydrophobic, hydrophilic, or a composite of both and (2) the membrane mass transfer resistance is not always negligible. Ensuring that the right fluid occupies the membrane pores vis-à-vis the affinity of the solute in the two phases can minimize membrane resistance. These aspects have been discussed in detail in Refs. [6,86,87].

Membrane contactor applications in the liquid–liquid extraction field fall in two categories: (1) removal of unwanted species from water and (2) removal and recovery of valuable species from water. Many investigations have been conducted over the year by academia as well as by industry. Below we are providing some samples from the wide range of applications reported in literature. The examples presented are divided roughly into three sections: (a) biotech and pharmaceutical products, (b) industrial chemicals and VOC, and (c) metals.

Processes for production of ethanol and acetone–butanol–ethanol mixture from fermentation products in membrane contactor devices were presented in Refs. [88,89]. Recovery of butanol from fermentation was reported in Ref. [90]. Use of composite membrane in a membrane reactor to separate and recover valuable biotechnology products was discussed in Refs. [91,92]. A case study on using membrane contactor modules to extract small molecular weight compounds of interest to pharmaceutical industry was shown in Ref. [93]. Extraction of protein and separation of racemic protein mixtures were discussed in Refs. [94,95]. Extractions of ethanol and lactic acid by membrane solvent extraction are reported in Refs. [96,97]. A membrane-based solvent extraction and stripping process was discussed in Ref. [98] for recovery of Phenylalanine. Extraction of aroma compounds from aqueous feed solutions into sunflower oil was investigated in Ref. [99].

Extraction of phenol from aqueous solution using hollow fiber membrane contactor was first investigated in Ref. [100]. However, the membrane used was not completely microporous. Instead, it was a dialysis-type membrane. A commercial plant to separate phenol from hydrocarbon fraction using microporous membrane contactors was reported in Ref. [101]. Soda lye was used to react with the phenol transferred from the feed phase to create and maintain the driving force for separation. This industrial-scale application enabled the processing of hydrocarbon fraction to a full-value raw material for phenol and acetone synthesis.

The first known commercial membrane-based liquid–liquid extraction system involved extraction of by-products from a wastewater stream using an aromatic solvent [102]. Before the membrane system was installed, the entire wastewater stream had to be incinerated leading to high costs for the gas fired incinerator per year. The membrane system lowered the contaminant concentration to adequate levels before the biological wastewater treatment plant, and saved significant operating cost.

A process to separate naphthenes from paraffins is claimed in Ref. [103]. It involves the use of a polar solvent for separation in a microporous membrane device. Use of membrane extraction to remove *p*-nitrophenol in wastewater from dye and pesticide synthesis was investigated in Ref. [104]. Removal of nonvolatile pesticide components from water is presented in Ref. [105]. Removal of several important organic pollutants such as phenol, chlorophenol, nitrobenzene, toluene, and acrylonitrile from wastewater was investigated in Ref. [106].

Removal of VOC contaminants from water was discussed in Ref. [107]. This particular process used sunflower oil to absorb the VOC compounds transferred from water across a gas-filled microporous membrane. However, to prevent any possibility of liquid breakthrough, a plasma-polymerized di-siloxane coating was applied on the oil side of the membrane. Report [108] presents results from a pilot trial where organic pollutants such as chlorinated organic compounds and aromatic organic compounds were removed from plant wastewaters.

Various investigators have also explored removal or recovery of metals from aqueous process or waste streams. Liquid–liquid extraction is particularly useful for metal removal since alternate technologies such as distillation are not feasible. A process to separate molybdenum from tungsten leachate using a microporous membrane was disclosed in Ref. [109]. Copper extraction in a membrane contactor using metal chelating agent was presented in Ref. [110]. Other applications suggested in literature include extraction of gold from aqueous solutions [111], removal of copper from edible oil [112], separation of yttrium from heavy rare-earth metals [113], removal of copper and chromium from wastewater [114], and extractions of mercury, copper, and nickel from water [115].

## 2.10 REVIEW OF MEMBRANE CONTACTOR DESIGN OPTIONS

Although membrane is the heart of the membrane contactor technology, appropriate internal design of the contactor device or module is critical for any commercial advancement of the technology. Internal design dictates how the two phases flow inside the contactor and how the hydrodynamics in each phase is managed. As shown in Equation 2.2, the rate of mass transfer is directly dependent on the mass transfer coefficients in each of the phases, which in turn is dependent on the internal hydrodynamics. As the devices become larger to serve large commercial-scale process capacities, dependence on internal flow management becomes more critical. The device design is also important in developing the processes for large-scale manufacturing of the contactors. In the following section, we are reviewing various design options investigated over the years.

Designs of membrane contactors with hollow fiber membranes fall in one of the two categories: (1) the primary fluid being treated flows through the inside (lumen) of the hollow fibers and (2) the primary fluid being treated flows on the outside (shell) of the hollow fibers. Another consideration is the flow direction of the fluid in each phase with respect to the axis of the membrane and with respect to each other. In most membrane contactors of early commercial designs, the contactor housing was of cylindrical shape with tube-in-shell configuration (as in tubular heat exchangers) where the primary fluid flows on the lumen side from one end of the fiber to the other and the other fluid flows on the shell side in parallel direction. This design is generally called the parallel-flow design and is illustrated schematically in Figure 2.5a. The contactors of such a design are relatively easy to manufacture. However, the main drawback of the parallel-flow design is the nonuniform spacing of hollow fibers and the resulting poor flow distribution or flow channeling on the shell side, particularly as the contactor diameter increases.

A significant improvement over this parallel-flow design is the transverse-flow design where the primary fluid flows on outside of the hollow fiber membrane at a transverse direction to the fiber axis, while the other fluid flows on lumen side of the hollow fibers. The relative merits of the two designs were first analyzed comprehensively in Ref. [116]. It determined that transverse flow on shell side significantly improves the mass transfer coefficient compared to the parallel-flow design. However, it was still difficult to ensure that the transverse flow on shell side is completely uniform along the fiber length. Most investigations on membrane contactors continued to focus on parallel-flow design, since they are easier to fabricate on small scale. The effect of shell side hydrodynamics in parallel-flow contactors was investigated and reported in Ref. [117].

The twin problems of (1) ensuring transverse flow uniformly along the length of fibers and (2) ensuring even flow distribution on shell side were solved largely by adopting the concept of hollow fibers in fabric array form that was wound around a central hollow mandrel with porous wall. The shell side fluid could be introduced in the membrane contactor through the central distribution mandrel. It could then flow radially outward, in a direction transverse to hollow fiber axes. The central

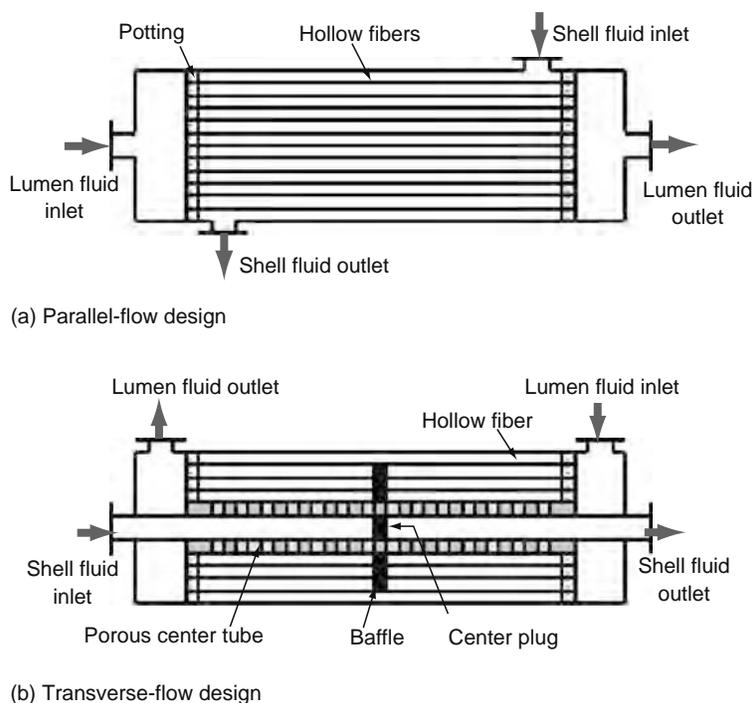

FIGURE 2.5 Primary design options for membrane contactors.

hollow mandrel ensures axial uniform flow distribution whereas the hollow fiber array ensures constant fiber-to-fiber distances and uniform transverse-flow distribution. A further improvement was the use of one or multiple flow-directing baffle inside the shell, just as practiced in commercial heat exchangers, which made the contactor more efficient and facilitated commercial production. Figure 2.5b schematically illustrates a transverse-flow contactor with flow-directing baffle. Detail investigations of this design are shown in Refs. [118–120], and both cylindrical and rectangular contactors are investigated in Ref. [118].

An interesting variation of the contactor design with baffle is disclosed in Ref. [121] for a degassing application. This shows a spiral-wound contactor similar to that shown in Ref. [120], but the baffle was placed on the gas side of the device and the water flow was on lumen side. Since most of the mass transfer resistances in liquid degassing process are essentially in the liquid phase, it is not clear how such a design would improve the hydraulic efficiency of the device.

In addition to what was discussed above, there have been many other contactor designs proposed over the years. A membrane contactor of rectangular design is disclosed in Ref. [122] made by laminating hollow fiber fabric sheets, and preventing flow channeling by specifying the densities of the hollow fibers and the warp fiber of the fabric. A similar structure of membrane contactor apparatus is claimed in Ref. [123]. Reference [124] discloses a contactor with multiple frames of square, polygonal, or circular, where the longitudinal directions of the fibers or tubes of adjacent frames are substantially perpendicular to each other. Stackable sub-modules with multiple frames of hollow fiber membranes in each sub-module were suggested in Ref. [125]. A rectangular contactor was also suggested in Ref. [75]. A tubular hollow fiber membrane contactor of parallel-flow design, with special spacers on shell side to reduce flow channeling, was disclosed in Ref. [50]. A radial-flow transverse-flow membrane contactor without any flow-directing baffle was shown in Ref. [126]. In some applications, particularly in degassing processes using deep vacuum, it has been shown that presence of flow-directing baffle such as claimed in Ref. [119] could actually be detrimental to performance because of internal diffusion in the gas phase. A hollow fiber membrane contactor that does not use a shell at all has been disclosed in Ref. [127].

## 2.11 COMMERCIAL OR PRECOMMERCIAL INSTALLATIONS OF LARGE-SCALE MEMBRANE CONTACTORS

Applications of membrane contactor technology in commercial processes are in various stages of development. Early success has come mainly in water degassing or gas addition applications. Membrane contactor systems of a wide range of flow capacities are currently in operation in various parts of the world. Systems with large capacities were possible only after membrane contactors of sufficiently large size and cost competitiveness could be produced commercially on a routine basis. Currently, the largest known commercially produced membrane contactor module has an active contact area of about 220 m<sup>2</sup> [128]. Commercial availability of such products has greatly facilitated the large-scale acceptance of this technology. A few examples of various installed contactor systems are provided below.

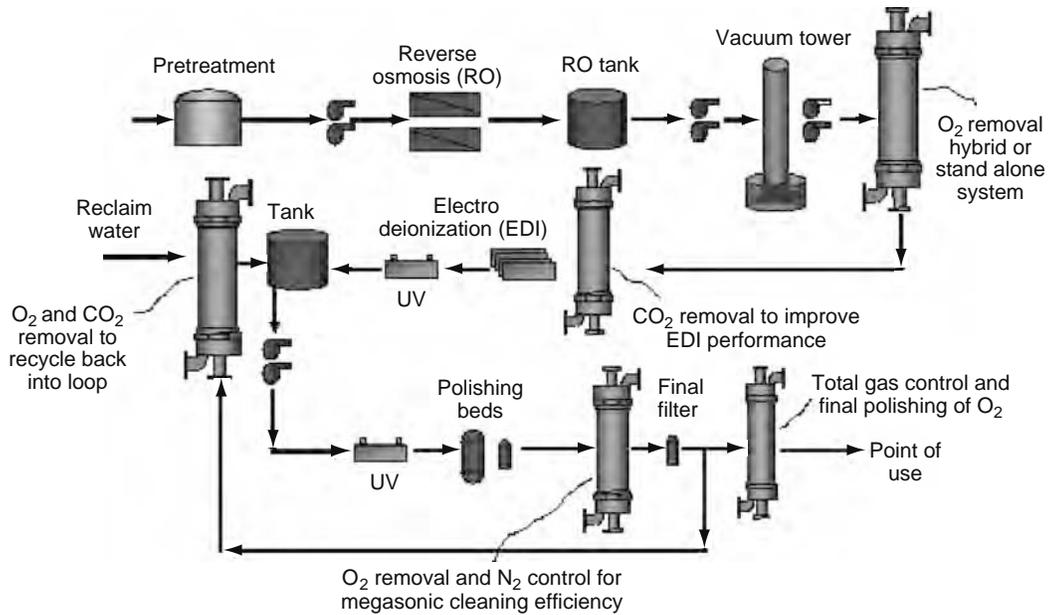

FIGURE 2.6 (See color insert following page 588.) Part of semiconductor plant ultrapure water production process.

Figure 2.6 schematically illustrates sections of a typical semiconductor ultrapure water (UPW) production process in a semiconductor plant. The water circuit consists of two main sections: (1) makeup (or central) system and (2) polishing loop, which provides water at the point of use. There are multiple locations in such a water process where membrane degassing could be needed as shown in the figure. Reverse osmosis is mostly used in makeup line as the primary purification means in such processes. In the past, large and inflexible vacuum towers were frequently used after RO to remove dissolved gases, such as O<sub>2</sub>, N<sub>2</sub>, and CO<sub>2</sub>. Membrane contactors are the norm today for replacement or supplement to vacuum towers in makeup lines, as shown in Figure 2.6.

A second place where membrane contactors are often used is before the electro deionization (EDI) step in UPW plants to remove residual CO<sub>2</sub> gas. Removal of CO<sub>2</sub> improves efficiency of EDI unit. Membrane contactors allow the opportunity to decarbonate water inline and under pressure just prior to EDI.

Contactors are also used in polishing loop for final degassing and to treat recycled or reclaimed water (Figure 2.6). The exact UPW process configuration depends on the specific needs in the plant and on quality of water supply to the plant. But no

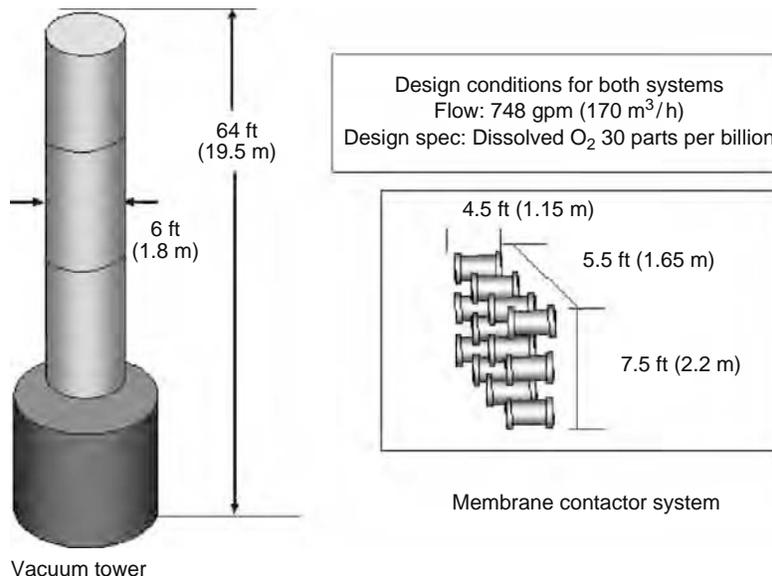

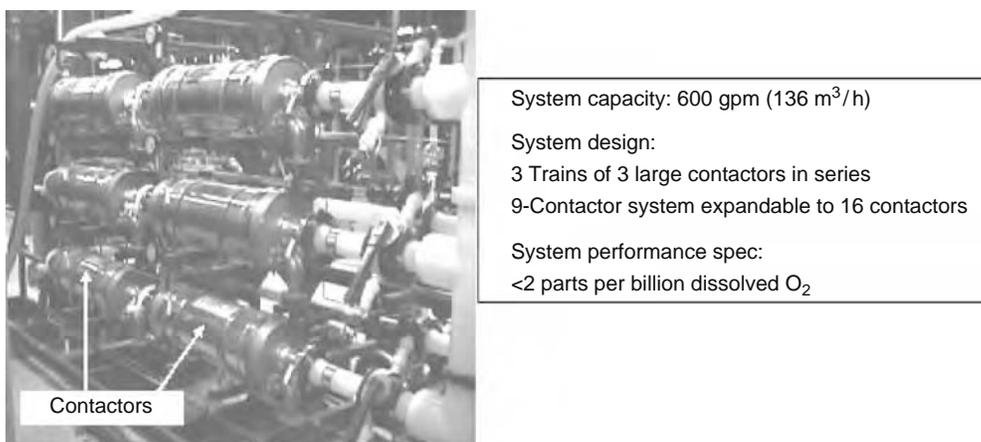

FIGURE 2.7 Relative system sizes of vacuum tower and membrane contactors.

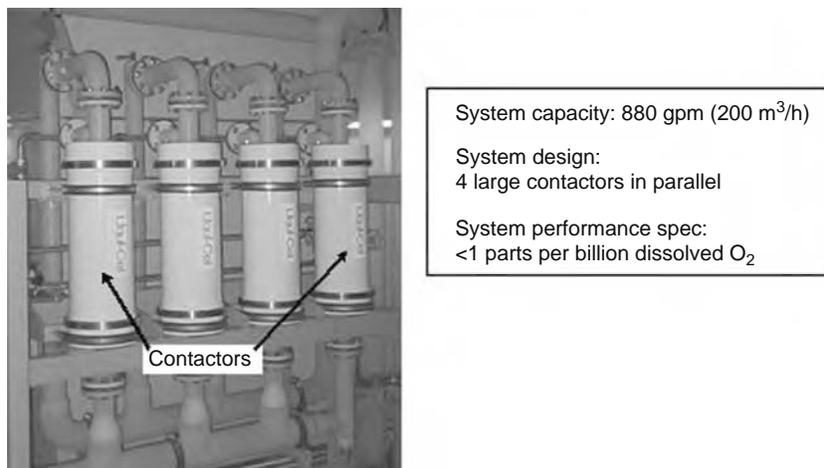

**FIGURE 2.8** Central ultrapure water degasification system.

matter what configuration is adopted, membrane contactors are used in most of the modern plants because of their various advantages (smaller footprint, flexibility, and cost). As Figure 2.7 shows membrane systems occupy much smaller space and eliminate need for ground preparation or a permanent structure.

Figures 2.8 and 2.9 show photographs of commercially installed membrane contactor systems. Figure 2.8 shows that of a central UPW degasification system and Figure 2.9 that of a polishing loop degasification system in a DRAM facility. Each system is built from large membrane contactor modules. As explained earlier, one advantage of a membrane contactor system is the modularity. Similar size contactors could therefore be used in large or small UPW research degasification systems. Figure 2.10 shows the photo of a smaller capacity water supply system used in a research facility.

Another frequent use of membrane contactors is to help optimize the deionization step in water purification systems. The contactor is placed between the cation exchange bed and anion exchange bed (Figure 2.11). The pH after the cation bed is very low, which favors formation of gaseous CO<sub>2</sub> from bicarbonates present in water. By using a membrane contactor, most of the bicarbonate alkalinity can be removed from water as CO<sub>2</sub>, thus significantly reducing the load on the anion exchange bed that follows the contactor. The life of the anion bed can be doubled or tripled using contactor, resulting in large cost savings. In addition, sizes of the cation and anion beds could be equalized, helping in cost savings. Compared to existing technology, the membrane contactor is less expensive to operate and can operate in a closed system with little minimal chance of external contamination.

Boiler feed water is another excellent application for membrane degasification. Dissolved oxygen is unwanted in boiler feed water. Lowering dissolved oxygen level saves chemical costs and reduces blow down costs and energy costs. Figure 2.12 shows a typical schematic flow diagram in a boiler plant. As shown in this figure, degassing steps can be implemented in more than one location in such plants. A photograph of an actual installed membrane degasifier system is shown in Figure 2.13.

**FIGURE 2.9** (See color insert following page 588.) Polishing loop degasification system.

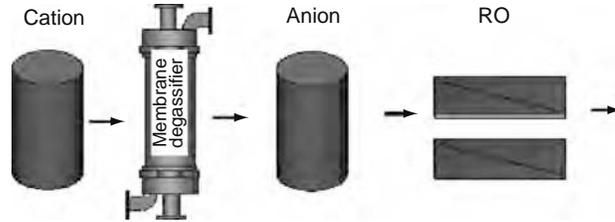

FIGURE 2.11 Membrane contactor to reduce size of anion exchange bed.

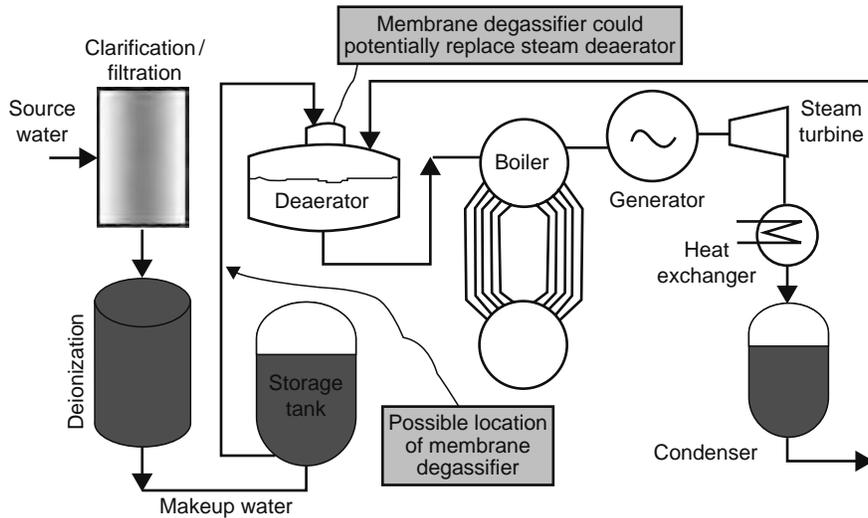

FIGURE 2.12 Schematic diagram of a boiler plant.

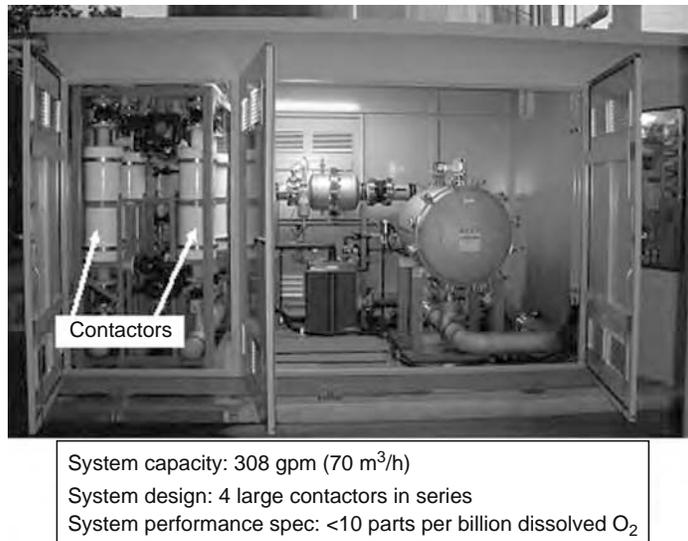

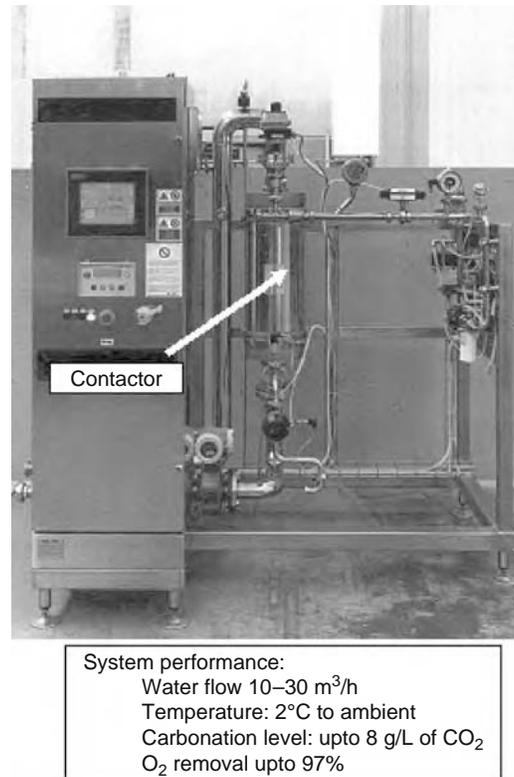

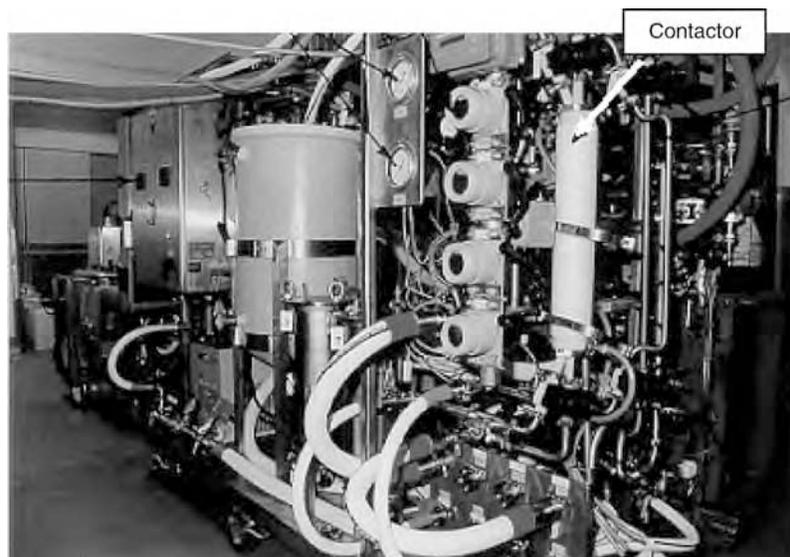

FIGURE 2.13 (See color insert following page 588.) Boiler water degasification system using membrane contactors.

**FIGURE 2.14** Membrane contactor for simultaneous carbonation and deoxygenation.

A photo of a small-scale membrane contactor system that could be used to simultaneously carbonate and deoxygenate water is shown in Figure 2.14. This is accomplished by passing CO<sub>2</sub> gas stream under pressure as a sweep on the lumen side of the contactor while water flows through the shell side. Water absorbs CO<sub>2</sub> under pressure and becomes carbonated while the presence of excess CO<sub>2</sub> gas creates a driving force for removing dissolved oxygen from the water.

Membrane contactors can be used in osmotic distillation process to transfer water vapor, as discussed in Section 2.8. Such a process has been investigated as a means of concentrating fruit juice [58] using concentrated brine as the receiving phase for water vapor. A photograph of a pilot system is shown in Figure 2.15.

**FIGURE 2.15** (See color insert following page 588.) Membrane contactor for fruit juice concentration using membrane distillation process.

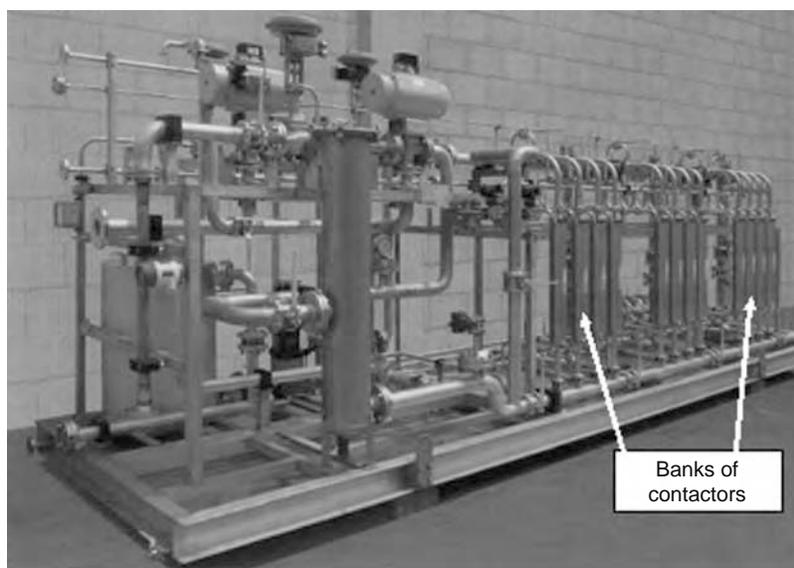

FIGURE 2.16 (See color insert following page 588.) Membrane contactors for liquid–liquid extraction.

Infusion of ozone into ultrapure water has become an excellent application of membrane contactors, as mentioned earlier. Ozone is generated in gas phase from air or oxygen, and the ozone-containing gas and ultrapure water are brought in contact with each other in the membrane contactor [50].

As mentioned in Section 2.9, liquid–liquid extraction has also been employed on a commercial scale in membrane contactors to remove environmentally toxic species from wastewater before incineration. Photograph of such a system is shown in Figure 2.16. Multiple banks of contactors are used in the system. The solvent used for extraction is returned to the chemical process that produces the toxic compounds.

In conclusion, membrane contactor technology has been creating a distinct application base for itself in recent years. The installed base of membrane contactors is still small compared to other membrane technologies. However, use of this technology cuts across diverse industries and markets, and in many instances membrane contactors are enabling customers with new opportunities that did not exist before. Many well-known producers of membrane and membrane modules today offer commercial membrane contactors as part of their product portfolio. It is our belief that new installations of membrane contactors will continue and new applications of this technology will be found in coming years.

## 3.1 INTRODUCTION

In the pharmaceutical and biotechnological industry, the downstream processing of fermentation broths normally involves numerous steps for biomass removal and product purification. In the early days of biomolecule purification, the only practical method used for protein separation from complex mixtures was based on protein precipitation by water miscible organic solvents [1]. Alteration of the solvent properties by the addition of neutral salts and organic solvents leads to precipitation of the macromolecule due to differences in solubility. Alternative processes including adsorption techniques, gel filtration, liquid phase partitioning, electrophoretic methods, and membrane technologies have been developed recently for protein purification. Adsorption techniques often result in purification steps that give the greatest increase in protein purity. Therefore, they became widely employed especially when adopted in combination with chromatographic and membrane processes.

Column chromatography is a highly developed method used as a final step (in both capturing and polishing) in the purification of biomolecules out of crude mixtures. Despite their large static adsorption capacity, conventional stationary phases involved in chromatographic separations are generally not suitable for operating with high linear velocities of the mobile phase. The first chromatographic columns were realized in packed beds with  $\sim 100 \mu\text{m}$  beads. Their main drawback is the compression and compaction at high velocities [2]. The pressure drop over the column is high even for low flow rates and increases during

**FIGURE 3.1** Evolution of affinity column bed geometry: (a) packed bed (100  $\mu\text{m}$  beads), (b) short “fat” bed (1  $\mu\text{m}$  beads), and (c) microporous hollow fiber (pore size  $>1 \mu\text{m}$ ).

the process time due to bed consolidation and plugging. For a given pressure drop across the bed, the throughput is inversely proportional to the bed height. For these reasons other column configurations were investigated, which range from stacked configurations (a number of short beds connected in series–parallel combinations) to radial flow arrangements (a short, wide bed curled up end-to-end upon itself).

For an efficient use of the adsorptive sites inside the chromatographic support, a certain residence time dependent on the particle size and porosity is required. Short diffusion distances lead to fast flows of the feed solution. This results in the development of chromatographic columns with smaller diameter particles, with the drawback that smaller particles pack more densely and create higher pressure drops. The pressure drop in conventional chromatographic columns with particles with a diameter of 2  $\mu\text{m}$  is usually high, up to 25 MPa [3]. The use of nonporous, rigid particles as chromatographic media can partially solve this problem. Furthermore, for such supports, the ligands are located on the particle surface and not inside the pores, thus the solute diffusion into the particle pores is no longer a limiting factor allowing for much faster mass transfer. Unfortunately, the use of nonporous supports usually causes lower protein-binding capacities (due to a small binding surface), low reproducibility, and high process costs [4]. Micropellicular stationary phases, prepared by coating a very thin sorbent layer onto the nonporous particle surface, also showed improved chromatographic characteristics [5].

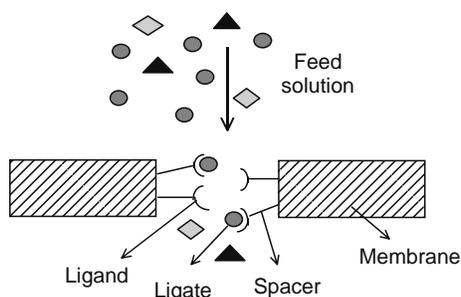

In the last few decades, in parallel with the development of nonporous chromatographic particles, new types of stationary phases including perfusive and super-porous beads were investigated. The particles for perfusion chromatography have large, interconnected canals allowing the solute molecules to pass quickly through the support at lower backpressure. Moreover, the binding capacity for perfusive media is higher than for nonporous supports leading to a more efficient separation process [6,7]. Furthermore, since neither binding capacity nor flow rate is the limiting factor, the scaling up of a perfusive chromatographic column can be relatively easy.

A different approach to lowering the pressure drop present in classical packed beds was the development of chromatographic shallower adsorption columns with larger cross section. In fact, the ideal column has an infinitely short bed height to minimize operating pressure and maximize throughput, and an infinite width so that the ligand loading and binding capacity are maximized. In recent years, hollow fiber membranes have also been proposed as an attractive alternative to porous beads as an affinity substrate in chromatographic separation processes (Figure 3.1).

In this chapter, the latest developments in stationary phases based on membranes (affinity membranes as well as mixed matrix membrane adsorbers) and monolithic separation media (both organic and inorganic) will be discussed. In the following sections, we first give some background information regarding the new types of chromatographic supports, focusing on the membrane materials, their properties, and preparation. Membrane activation and ligand coupling are discussed separately for polymers containing different types of functional groups. Advantages of membrane chromatography, as well as an introduction to the mass transfer in different affinity supports, are then presented. An outlook to possible applications of the chromatographic membranes in various process conditions is finally given.

### 3.2 NEW TYPES OF MEMBRANE CHROMATOGRAPHY SUPPORTS

The chromatographic separation process based on membranes has recently become an attractive and competitive method for purifying proteins and other biomolecules from biological fluids [8–13]. The membrane chromatographic system was originally designed to bypass the fundamental limitations of packed-bed adsorbers. The system consists of one or more microporous membranes as stationary phase, carrying adsorptive moieties based on ion exchange, affinity or hydrophobic interactions. The individual membranes can have different geometries, from disks, flat or layered sheets to full or hollow fibers. Since the

**FIGURE 3.2** Principle of affinity membrane chromatography.

adsorption capacity of a single membrane is limited, multiple membrane layers may be stacked together in series and housed within the filtration modules. Depending on the type of module involved in the separation process, different operation modes (dead-end, cross-flow, or radial flow) may be used.

Based on a literature survey, affinity-based chromatography seems to be the largest segment in membrane chromatography. In affinity membranes, the ligand is immobilized on the membrane surface (Figure 3.2). When the solution containing the compound of interest is filtrated, the desired molecule binds selectively and reversibly to the ligand immobilized on the membrane surface. In case of sterical hindrance the so-called spacer molecule can be introduced between the polymeric support and the ligand. These spacers permit free rotation of the ligand and thus provide more opportunities for the orientations necessary for ligand–ligate complex formation to occur. The conditions of the surrounding milieu determine the stability of the ligand–ligate complex. Changes in the physical or chemical environment conditions can disrupt the biological complexes.

In chromatographic separations using flat sheet membranes, compact porous disks, fibers, tubes, or rods, the interaction between the ligate molecule and the immobilized ligand takes place in the through-pores of the matrix and not in the dead-end pores of the conventional packed-bed particles. This method resembles affinity membrane separation with a very short affinity chromatography column [2].

Solid phase extraction using particle-loaded membranes (mixed matrix membrane adsorbents) and particle-embedded fibers became a widely used laboratory technique to isolate and concentrate selected analytes before chromatographic processes [14,15]. The incorporation into a porous polymeric membrane of functional particles, such as silica and its derivatives (containing, for example, ethyl, butyl, phenyl, octyl, octadecyl, or cyanopropyl functional groups), styrene/divinylbenzene-based ion-exchange resins, or fibrous cellulose derivatives, results in adsorptive structures that can be applied to isolate peptides, proteins, nucleic acid, or other organic compounds from complex mixtures [16–18]. Most suitable particles display, in combination with the porous matrix morphology, rapid adsorption kinetics, a capacity and selectivity commensurate with the specific application and allow for fast desorption of the targeted molecule. The affinity of suitable adsorptive particles for specific molecules can be defined in terms of hydrophobic, hydrophilic or charged functionalities, molecular (imprinted) recognition, or other specific interactions. However, these materials differ from the classical affinity membranes because the binding process takes place at the small particles embedded in the porous matrix and not at the pore wall itself. Nevertheless they show hydrodynamic advantages similar to those of the adsorptive chromatographic membranes.

Monolithic stationary phases (also called continuous beds) have emerged as an alternative to traditional packed-bed columns since the late 1980s, due to their easy preparation with good reproducibility, versatile surface chemistry, low backpressure, and fast mass transport. Their advantages are similar to membrane chromatography, but differ from the classical membrane media in terms of material, preparation, and morphology [19–21]. The monoliths are prepared mainly by in situ polymerization of organic species or silicon alkoxides and consolidation inside the column. Fusion of the porous packing material inside the column tubing by a sintering process has also been reported. As a result of the polymerization conditions (ratio and concentration of monomer and cross-linker, temperature and presence of porogenic solvents), the bed macroporous structure can be adjusted. If necessary the surface modification of the obtained porous matrix may be performed to improve the chromatographic-binding capacity.

The monoliths usually possess a bimodal pore size distribution consisting of large micrometer-size through-pores (which allow the liquid to pass through the matrix under low pressure even at high flow rates) and much smaller pores in the 10 nm range that contribute significantly to the overall surface area. Due to their well-defined bimodal pore size distribution, the monolithic supports provide high separation power offering good chemical stability and flow characteristics [22]. The continuous beds have a longitudinal dimension usually exceeding their lateral dimension. This brings the monoliths closer to the packed-bed columns than to membrane chromatography. Nevertheless, they were recently successfully used for high-speed separation in reverse-phase, ion exchange, hydrophobic interaction, or affinity modes especially for separation of biomolecules.

### 3.3 TYPES OF MATERIALS USED IN ADSORPTIVE MEMBRANES PREPARATION

Numerous natural and synthetic polymers such as polysaccharides, polyamide, polysulfone (PSf) and its derivatives, polyethylene and polypropylene, acrylic copolymers, polycarbonates, polyvinyl alcohol, have been explored as potential materials in chromatographic processes. The substrates used in successful membrane chromatography applications should fulfill several conditions including: (i) high macroporosity with large internal and external surface areas to maximize interaction of matrix-bound ligands with the ligate during the binding step; (ii) high mechanical stability and resistance to compaction under pressure; (iii) high chemical and physical stability under harsh conditions used for the ligand coupling and ligand–ligate complex formation; (iv) hydrophilic surfaces to minimize the nonspecific adsorption of bioactive species, and to minimize competition for the desired ligates; and (v) high density of reactive groups for subsequent coupling of spacer arms and ligand molecules [8]. Because very few materials fulfill these conflicting requirements, the choice of the support for a particular application is very often a compromise among the above-mentioned conditions. In this section, a number of often-used support materials is described.

Polysaccharides including cellulose and its derivatives, agarose, dextran, starch, chitin, and chitosan (Figure 3.3) have been widely used as a support material in affinity chromatographic separations.

Celulose is a 1,4- $\beta$ -linked D-glucose linear polymer with occasional 1,6-bonds (Figure 3.3a), derived both from plant and bacterial sources. The glucose segments contain three hydroxyl groups that are very susceptible to chemical reaction, forming esters (cellulose acetate, cellulose nitrate) and ethers (ethyl cellulose) and allowing for easy ligand immobilization.

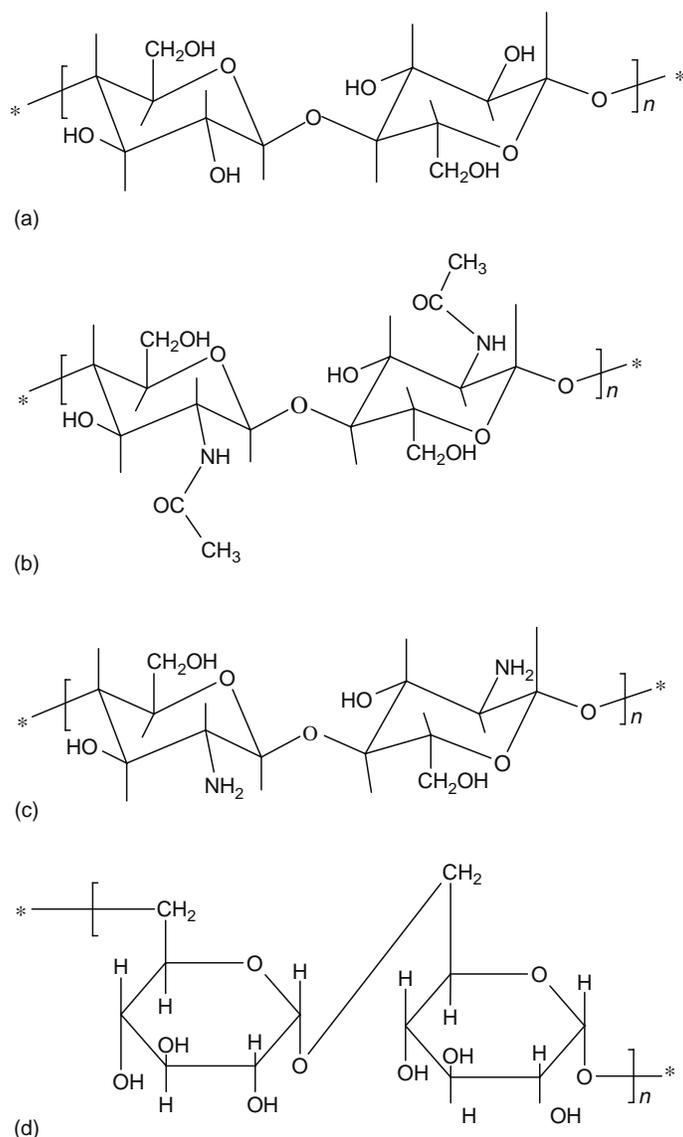

FIGURE 3.3 Structure of polysaccharides (a) cellulose, (b) chitin, (c) chitosan, and (d) dextran.

The commercially available cellulose is generally cross-linked with a bifunctional reagent such as epichlorohydrin and is remarkably stable to chemical attack. The glycosidic linkage is susceptible to acid hydrolysis, which under extreme conditions can yield almost quantitative amounts of pure crystalline D-glucose. Oxidizing agents such as sodium periodate can generate aldehyde groups and carboxyl groups.

Native cellulose imbibes only 30%–40% water compared with agarose that can hold 8–16 times its weight of water. The limited cellulose swelling results in a small available pore surface and unfortunately is associated with relatively small pores. This makes the number of applications of native cellulose in membrane chromatography quite low. Special procedures are necessary to produce cellulose disks, films, or other formats, which permit diffusion of large proteins into the structure. Nevertheless, several methods for the preparation of stable macroporous cellulose membrane as well as composite cellulose membranes were proposed in the literature [23–31]. The new types of cellulose microfiltration membranes (based mainly on regenerated cellulose, hydroxyethyl cellulose [HEC], and cellulose acetate) are characterized by high levels of water imbibition and by much larger pore sizes. Additionally, they present hydrophilic surfaces hence a low nonspecific adsorption and abundant functional groups.

Guo et al. [23] prepared epoxypropane chloride cross-linked macroporous cellulose affinity membranes with triazine dyes ligands. These membranes consist of coarse fibers with high porosity and large pores but with a less uniform morphology. The preparation of diethylaminoethyl-derivatized cellulose membranes with high protein loading was reported by Gerstner et al. [25]. The membranes were used for preparative-scale separation of cytochrome, lysozyme, and  $\alpha$ -chymotrypsinogen. Chen et al. [26] prepared a modified cellulosic microfiltration membrane by blending cellulose acetate with polyethyleneimine followed by cross-linking with polyisocyanate. These membranes were investigated in affinity processes for metal chelating, removal of endotoxins, or ion-exchange separations. Composite membranes of cellulose with grafted acrylic polymers [27,28] or blends of polyethersulfone and polyethylene oxide coated on all surface with a covalently bound layer of HEC were also prepared [29,30]. Yang et al. [31] prepared composite cellulose membranes containing epoxide functional groups via grafting polymerization of glycidyl methacrylate to dispersed cellulosic fibers. The obtained membranes possess high porosity and good flow characteristics and could be further modified for affinity ligand coupling.

Cellulose-based monoliths prepared from cross-linked sponge-like regenerated cellulose with a continuous, interconnected, open pore structure (50–300  $\mu\text{m}$ ) are commercialized by Sepragen under the trade name Seprasorb and are available for ion-exchange chromatography.

Chitin and its deacetylated product Chitosan are good biological materials due to their easy availability, hydrophilicity, biocompatibility, and chemical reactivity. They can be obtained on a large scale from the outer shells of crustaceans and have numerous potential applications in biomedicine, biochemistry as well in pharmaceutical or chemical industries. Both have a structure similar to that of cellulose, possess a large number of reactive groups ( $\text{CH}_2\text{OH}$  in chitin and chitosan, or the more reactive  $\text{NH}_2$  in chitosan, Figure 3.3b and 3.3c), and can be easily modified to meet various needs. Chitin is usually insoluble in acid and basic solutions as well as in common organic solvents. Therefore, preparation of macroporous chitin membranes by the usual phase inversion method is difficult. However, acetylated chitin membranes with good chemical and mechanical properties were prepared by acetylation of chitosan macroporous membranes [32].

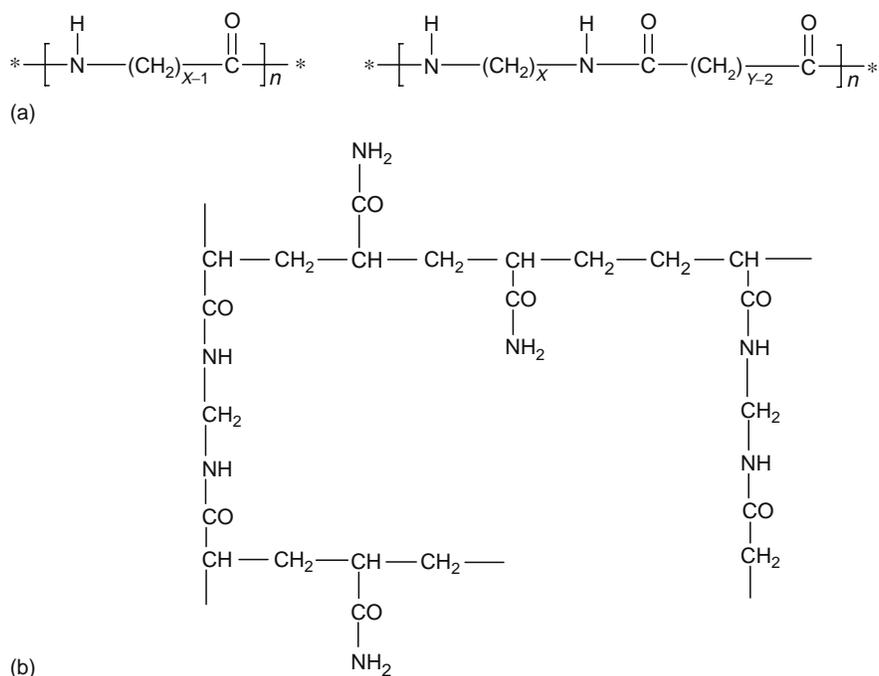

Chitosan is, on the other hand, soluble in acidic solutions and has an excellent film-forming ability. Microporous chitosan membranes were prepared by phase inversion method and subsequently coupled with various types of ligands to generate chitosan affinity membranes [32–34]. Zeng et al. [32] prepared macroporous chitosan membranes using silica particles, which in contrast with chitosan, are insoluble in acidic solutions and soluble in basic ones. A dope solution of acidic aqueous chitosan and silica particles was poured on a glass plate after which the water was evaporated. The dried formed films were immersed into an aqueous NaOH solution under heat conditions to dissolve the silica particles. The obtained macroporous membranes were reported to have controlled porosity and pore sizes, and good mechanical strength. To prevent dissolution in acidic media, the chitosan membranes can be cross-linked with epichlorohydrin or ethylene glycoldiglycidyl ether (EGDGE).

Due to its good properties chitosan was also employed in preparing composite membranes. Klein et al. [35] reported the preparation of chitosan-coated sulfonated poly(ethersulfone) membranes as affinity chromatographic supports. Through the use of the charge attraction, the chitosan is localized at the fiber surface and subsequently cross-linked in situ with EGDGE, which also supplies new reactive groups. These coatings are not covalently linked to the supporting fiber, but rely on the insolubility of the cross-linked coating for stability. The hydroxyl and amino glucose repeated units can be further modified to bind the affinity ligand.

Dextran, a linear water-soluble polysaccharide composed of more than 90% 1,6-linked  $\alpha$ -D-glucose (Figure 3.3d), is produced by fermentation of sucrose by microorganisms of the genus *Leuconostoc*.

The soluble linear dextran chains are cross-linked with epichlorohydrin in alkaline solution to yield a three-dimensional gel, which solidifies exothermically. The commercially available dextran gels (Sephadex) are very stable to chemical attack and can be heated up to 110°C in an autoclave for 40 min without impairment of properties. The gels swell to some extent in ethanol, ethylene glycol, formamide, *N,N*-dimethylformamide (DMF), and dimethylsulfoxide (DMSO).

Dextran is mainly used as a coating material on available microfiltration membranes. Breifs and Kula [36] reported the use of dextran-coated nylon membranes as affinity media. The ligand was first coupled with dextran (both by adsorption and

**FIGURE 3.4** Structure of (a) aliphatic polyamides (nylon- $x$  and nylon- $x$ - $y$ ) and (b) polyacrylamide.

covalent reactions), followed by attachment of the ligand-coupled dextran to the inner porous surface of a trichloro-triazine activated nylon membrane. Tang et al. [37] also prepared dextran-coated nylon membranes as glucose-sensitive hydrogel membranes. They used a polymer produced by cross-linking of two dextrans with different molecular weights. The smaller dextran was functionalized with covalently grafted concavaleine A (conA). This material was mixed with a larger, non-functionalized dextran, allowing easy control of the overall amount of grafted conA in the material. The mixture was cast on a porous nylon support, which provides mechanical strength, between two glass plates using spacers to give the required total membrane thickness.

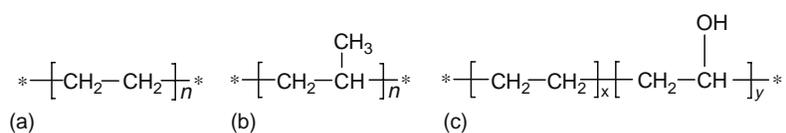

Polyamides are synthetic amides in which recurring amide groups ( $\text{---NHCO---}$ ) are an integral part of the main polymer chain. A large number of polyamide types, both aliphatic and aromatic, with very different properties are commercially available. The schematic structure of the basic aliphatic polyamides referred to as nylons is presented in Figure 3.4a. Aromatic polyamides are good membrane materials because of their outstanding mechanical, thermal, and chemical stability but aliphatic polyamides such as nylon-6, nylon-6-6, or nylon-4-6 are of greater interest as microfiltration membranes.

Nylon is known to be resistant to a large number of organic solvents, partly because of its crystalline nature. It is also highly resistant to aliphatic and aromatic hydrocarbons as well as to some linear alcohols and aprotic liquids such as  $n$ -methylpyrrolidone or dimethylformamide. However, nylon membranes only have a low concentration of terminal amino groups to serve as functional groups for ligands coupling. They also present a high nonspecific adsorption of biomolecules during affinity separation processes. Therefore, hydrolysis of nylon membranes is necessary to both increase the active groups and prevent electrostatic interaction with proteins.

Although the hydrophobic surface of nylon membranes may be improved by hydrolysis or chemical modification, composite polyamide membranes are preferred in chromatographic applications. Klein et al. [38] prepared polyamide microporous membranes by modification of terminal amino groups. The density of activation sites for ligand coupling is increased by covalent binding of a polyhydroxyl-containing material to the polyamide membrane by reaction with the activated terminal groups. Composite nylon membranes prepared by coating of HEC on microfiltration polyamide membranes were also reported by Beeskow et al. [39]. HEC was immobilized on the pre-activated nylon membrane surface via amino end-groups or amide groups in the nylon chain. Subsequently the HEC hydroxyl groups were activated with epichlorhydrin or bioxirane to bind specific ligands suitable for affinity chromatography.

The neutral hydrophilic polyacrylamides are entirely gels formed by copolymerization of acrylamide ( $\text{CH}_2=\text{CH---CONH}_2$ ) with the bifunctional cross-linking agent,  $N,N'$ -methylene-bis-acrylamide ( $\text{CH}_2=\text{CH---CONHCH}_2\text{NHCO---CH}=\text{CH}_2$ ) (Figure 3.4b).

The ratio and concentration of acrylamide to that of the cross-linking agent in the reaction mixture can be varied to give an infinite series of insoluble covalently bonded gel products that differ in their average pore size. The polyacrylamide gels are chemically stable in dilute solutions of salts, detergents, guanidine-HCl, urea, and most organic solvents. They are nevertheless

**FIGURE 3.5** Structure of (a) polyethylene, (b) polypropylene, and (c) polyvinyl alcohol-*co*-ethylene (EVAL).

hydrolyzed at extreme pH or by nitrous acid to yield carboxyl functions. The gels are biologically inert and generally are not subject to enzymatic digestion or metabolism by microorganisms.

The principal advantage of polyacrylamide in chromatographic processes is polyacrylamide possesses an abundant supply of modifiable groups, which allows the covalent attachment of a variety of ligands. The use of polyacrylamide carriers for affinity separations has nevertheless been limited. Principally this appears to be the result of the low degree of porosity of the beads currently available and to the shrinkage observed during the chemical modifications required for attachment of the ligand. However, Gupta and Anjum [40] prepared ion-exchange polyethylene-*g*-polyacrylamide membranes via graft polymerization of acrylamide onto polyethylene films using a pre-irradiation method. The alkaline hydrolysis of radiation-grafted polyethylene-*g*-polyacrylamide films transformed the amide groups into carboxyl groups, resulting in membranes with good binding capacity for mercury ions.

Composite membranes of cellulose and acrylamide polymer are also produced by Cuno Life, Meriden, USA. The Zeta Plus H series of filter cartridge employs two layers of graded-density filter media, the upstream layer consisting of a more open structure compared to the downstream layer. This allows the upstream layer to essentially act as prefilter, retaining large particles, yeast, and colloids, while the tighter downstream layer removes remaining microorganisms and haze components.

Hjerten and his research group [41] introduced monolithic columns based on acrylamides as chromatographic separation media in the late 1980s. Xie et al. [42] prepared rigid porous polyacrylamide-*co*-butylmethacrylate-*co*-*N,N'*-methylene-bis-acrylamide monolithic column for hydrophobic interaction chromatography. They also prepared polyacrylamide-*co*-*N,N'*-methylene-bis-acrylamide monolithic rods and studied the effect of polymerization conditions on rods' morphology.

Polypropylene, polyethylene, and its copolymers, including polyvinyl alcohol-*co*-ethylene (EVAL) and polyethylene-*co*-maleic anhydride, are often reported in the literature as affinity supports for different ligand chemistries (Figure 3.5). Bare polyethylene and polypropylene membranes have good thermal, mechanical, and chemical resistance but are inert and show a too high nonspecific adsorption of biomolecules. Therefore, an additional surface modification step is necessary to introduce various functional groups and to decrease the surface hydrophobicity. Microporous polyethylene and polypropylene membranes were grafted with various monomers, containing ion-exchange groups ( $-\text{NH}_2$ ,  $-\text{SO}_3\text{H}$ ,  $-\text{COOH}$ ), such as sodium styrenesulfonates, vinyl acetate, hydroxyethyl methacrylate, or glycidyl methacrylates, to acquire active epoxide groups. The latest membranes can be further modified with ion exchange, metal chelate (iminodiacetate), or hydrophobic groups (butyl, phenyl, phenylalanine, or tryptophan) [43–46]. Kim et al. [43,47] reported the preparation of polyethylene microfiltration hollow fibers grafted with glycidyl-methacrylate, hydroxyethyl-methacrylate, or vinyl acetate followed by coupling of affinity ligands. The nonselective protein adsorption of the obtained membranes was obviously diminished while maintaining water permeability. Using radiation-induced graft polymerization of acrylic acid and glycidyl-methacrylate, Kiyohara et al. [48] carried out surface modification of porous polyethylene membranes to introduce succinimide and epoxy groups into the hollow fibers. The resulting membranes showed higher permeabilities and lower nonspecific protein adsorption.

Poly(vinyl alcohol-*co*-ethylene) is derived from copolymers of vinylacetate and ethylene by hydrolysis of the acetyl function of the ester comonomer. EVAL is a random copolymer carrying hydrophilic (vinyl alcohol) and hydrophobic (ethylene) segments in a single molecule (Figure 3.5c). It is insoluble in water and combines a good wet strength with hydrophilicity. EVAL shows good membrane characteristics for use in various kinds of blood purification devices, including hemodialyzer and plasma separation. The membrane properties are closely associated with the ratio of composition of hydrophilic groups to hydrophobic groups of poly(vinyl alcohol-*co*-ethylene). The polymer whose ethylene content is about 30% (molar) is nowadays involved in medical applications.

Commercial EVAL hollow fiber membranes prepared via the copolymerization of ethylene and vinyl alcohol have been recently explored for protein immobilization. L-histidine has been coupled onto EVAL-fibers activated with epichlorhydrin or butanediol diglycidyl ether to prepare an affinity support for immunoglobulin G (IgG) purification [49]. Furthermore, histidine-immobilized hollow fiber membranes have been employed for endotoxin removal from solutions of snake antivenom serum [50]. Avramescu et al. [51] prepared EVAL microfiltration membranes from the quaternary water/1-octanol/DMSO/EVAL system, using 1-octanol as non-solvent additive in the casting solution. To couple the affinity ligand, surface functionalization reactions in aqueous and organic media (via glutaraldehyde, oxiran, trichloro-*s*-triazine, and sulfonyl chloride reactions) as well as surface activation by a low-pressure glow discharge treatment, were performed. They also prepared EVAL porous membrane adsorbers with various ion-exchange particles incorporated into the matrix by an immersion phase separation process [52]. The prepared particle-loaded EVAL membranes were employed in protein recovery, as a protein concentration medium for the separation of similar-sized proteins with different isoelectric points and as adsorptive devices for endotoxin removal.

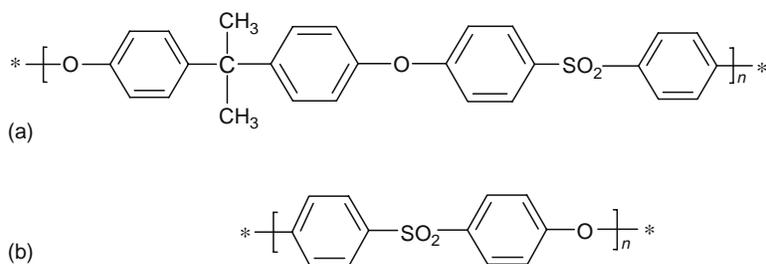

FIGURE 3.6 Structure of (a) polysulfone and (b) polyethersulfone.

Polysulfone and its derivatives mainly polyethersulfone (Figure 3.6) are suitable membrane materials because of their good film-forming properties and high thermal, chemical, and biological resistance. However, their strong hydrophobicity and nonwettability are usually undesirable in membrane chromatography.

Various methods to improve the characteristics of polysulfone membrane include preparation of copolymers with desired functionality, blending with hydrophilic polymers, surface coating, or introduction of hydrophilic groups into the polymer backbone. Klein et al. [29] modified microporous polysulfone membranes by reacting terminal phenol groups with EGDGE to produce terminal epoxy groups. These were used to covalently link HEC polymers to the membrane surface. Further epoxidation of the HEC and reaction with hexanediamine produced amine-terminated leashes on the microporous membrane. Heterogeneous polysulfone affinity flat filter membranes having chelating groups for  $\text{Hg}^{2+}$  were prepared by Wang et al. [53] via phase separation, using blends of chelating resin and polysulfone as membrane materials, *N,N*-dimethylacetamide as solvent, and water as extraction solvent. Higuchi et al. [54,55] modified the PSf fiber surface with propane sulfone and  $\text{SnCl}_4$  as catalyst obtaining membranes with low nonspecific protein adsorption. They also prepared PSf hollow fiber membranes containing hydroxide groups by a single-step reaction with propylene oxide and Friedel–Crafts catalyst.

Other polymeric materials (Figure 3.7) including polystyrene, polyvinylchloride (PVC), polytetrafluoroethylene (PTFE), polyvinylidene difluoride (PVDF), polyacrylonitrile (PAN), polycarbonates, polyacrylates and polymethacrylates, polyetherurethane, as well as various inorganic materials have been used as chromatographic supports.

Polystyrene and its derivatives (mainly chloromethylstyrene) are widely used in chromatography to prepare monolithic rods frequently using divinylbenzene (DVB) as cross-linker [20,21,56]. Polystyrene-*co*-divinylbenzene polymers possess good chemical and biological stability and due to their highly hydrophobic character can be used as reversed phases in chromatographic applications. Hydrophilic monolithic rods based on polystyrene have been also prepared by modification of 4-chloromethylstyrene with ethylenediamine followed by a  $\gamma$ -gluconolactone reaction, which provides the necessary degree of hydrophilicity [57].

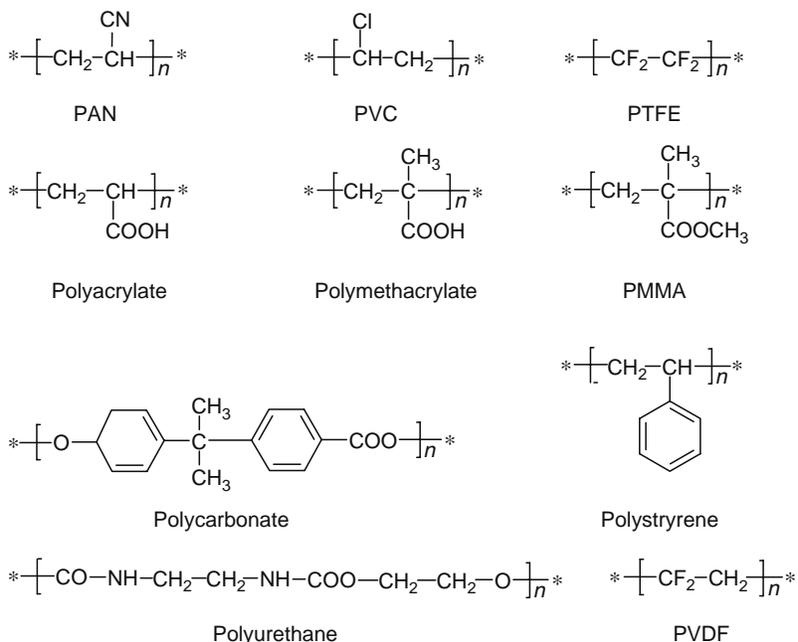

FIGURE 3.7 Structure of other polymers used in membrane preparation.

Acrylate- and methacrylate-based polymers are stable under extreme pH conditions, which cannot be tolerated by typical chromatographic packing materials, and can be easily functionalized using glycidyl methacrylates. Poly(glycidyl methacrylate-*co*-ethylene dimethacrylate) is the most frequently used material in the preparation of monolithic rod. Thin discs of macroporous poly(GMA-*co*-EDMA) have been synthesized by azo-bis-isobutyronitrile-initiated free-radical polymerization of a mixture of monovinyl and divinyl monomers in the presence of a porogenic agent [58–59]. The preparation route leads to controlled porous media with good mechanical strength and high density epoxy active groups, which provide reactive sites for further ligand coupling.

Porous affinity membranes based on hydrolyzed poly(GMA-*co*-EDMA) grafted with glycidyl methacrylates oligomers were also reported [2,60]. Tennikova et al. [2] prepared functionalized macroporous poly(GMA-*co*-EDMA) membranes by reaction with propane sulfone, diethylamine, or water, leading to the formation of corresponding sulfonic acid, diethylamino or diol-derivatized stationary chromatographic phases. Unfortunately, the poly(GMA-*co*-EDMA) membranes are mechanically weak and due to their hydrophobic character may cause nonspecific adsorption of proteins.

Hydrophilic microporous polyvinyl chloride membranes activated with glutaraldehyde or treated with polyvinyl imine (Acti-Disks) are produced by FMC Bioproducts. PVC membranes with embedded fibrous cellulose derivatives or functionalized silica beads were developed by Manganaro et al. [61]. A mixture of PVC powder, cyclohexane (as porogen), particulate materials, and water (as swelling agent) was cast into a sheet form. The solvent was extracted with hot water resulting in membranes with rigid structure, good chemical resistance, and low nonspecific adsorption.

Polytetrafluoroethylene (PTFE) microporous composite membranes were prepared in a similar way [62] using silica derivatives and ion exchange or iminodiacetate-cellulose resins embedded in the PTFE matrix and is used mainly for protein separation and water purification.

Dalven et al. [63] prepared various membranes with pore sizes ranging from 60 to 180 nm, using different copolymers of acrylonitrile and a vinyl comonomer containing arylamine, pyridine, or an aliphatic hydroxyl group. The obtained membranes proved to be suitable for protein immobilization, although various copolymers differed with respect to the weight loading of protein upon a membrane. Maximal protein loading was observed routinely with acrylonitrile-*m* aminostyrene membranes. Godjevargova et al. [64] surface-modified poly(acrylonitrile-methylmethacrylate-sodium vinylsulphonate) membranes with sodium hydroxide and hexamethylenediamine, hydroxylamine, and hydrazine dihydrochloride to introduce amino groups onto the porous surface. The membranes prepared from the modified copolymer possess the same porosity as the membranes of unmodified acrylonitrile copolymer. Glucose oxidase was immobilized on the hydroxylamine modified membranes, combining high activity with good thermal and storage stability.

Microporous polyetherurethane-urea membranes were prepared from DMAc and methylethylketone solutions by electrostatic spinning method [65]. The membranes were functionalized using isocyanate agents and further activated with succinimide, diimidazole, or sulfonyl reactions. Early attempts to prepare monolithic stationary phases involved open-pore polyurethane foams [66,67]. These monoliths possess not only good permeabilities but also high swelling ratios in different solvent classes, which made them inapplicable in large-scale chromatographic processes.

Hydrophilic polyvinylidene difluoride (PVDF) membranes prepared by a strong basic treatment of hydrophobic PVDF supports followed by grafting of glycine molecules onto their surface [68] showed good properties for downstream protein purification and immunoassays [69,70]. Activated acrylate coated microporous PVDF membranes (Immobilon) are also commercially available from Millipore.

Inorganic supports (including glass materials, ceramic, metallic, or zeolitic membranes) offer, when used in chromatographic separation processes, the advantage of high mechanical strength, regenerability, resistance to solvents, and microbial attack. The inorganic materials, such as alumina, bentonite, glass, nickel oxide, silica, and magnetic iron oxide powders, do not change the structure over wide temperature, pH, or pressure. Nevertheless, in operation processes their compressibility and resulting pressure drop increase that is a major obstacle for large-scale applications. Li and Spencer [71] prepared alkali-stable ion-exchange titanium dioxide membranes coated with polyethyleneimine (PEI). PEI ion paired with the oxide support was subsequently cross-linked with glutaraldehyde to form reactive films to which the affinity ligands can be coupled. The preparation of immobilized metal-chelate affinity membranes using glass hollow-fiber membranes as substrate was reported by Serafica et al. [72]. The microporous glass membranes were activated with glycidoxypropyl trimethyl silane to generate epoxide groups, to which iminodiacetate was coupled. The authors compared protein adsorption behavior on the prepared membranes with results from a mathematical model.

Despite the fact that the first silica monolithic supports have been already reported in the late 1970s, the first uniform porous silica rods used for reverse-phase chromatography were introduced in 1996 by Minakuchi et al. [73]. They were produced according to a solgel approach consisting of hydrolytic polycondensation of alkoxy silane in water in the presence of a water-soluble organic polymer and acetic acid as catalyst. The prepared rods possess 1–2  $\mu\text{m}$  size through-pores and 5–25  $\mu\text{m}$  mesopore size and can further be octadecylsilylated to give the  $\text{C}_{18}$  reverse phase. A second method for preparation of silica monoliths, similar to the one used to cast column end frits in fused-silica tubing for HPLC, was reported by Fields [74]. Although the method leads to continuous silica xerogels, the obtained materials possess heterogeneous morphologies.

### 3.4 ADSORPTIVE MEMBRANES PREPARATION

Many publications of the last decades reported the preparation, characterization, and performances of various types of adsorptive membrane. Ion exchange, affinity, reverse phase, or hydrophobic interaction membrane chromatography have been described. In the following, various methods involved in the preparation of different classes of adsorbers will be discussed.

#### 3.4.1 MEMBRANE PREPARATION IN AFFINITY CHROMATOGRAPHY

Since chromatographic membranes consist of a substrate to which the interactive ligand is coupled, three main steps are usually involved in their preparation: (i) basic membrane preparation; (ii) functionalization (activation) of the basic membranes; and (iii) spacer arms and ligand molecules coupling on the activated porous membrane surface [9]. The preparation of basic materials is essential for the performances of the separation process.

##### 3.4.1.1 Basic Membrane Preparation

Most of the available commercial microporous membranes such as polysulfone, polyethersulfone, polyamide, cellulose, polyethylene, polypropylene, and polyvinylidene difluoride are prepared by phase inversion processes. The concept of phase inversion in membrane formation was introduced by Kesting [75] and can be defined as follows: a homogeneous polymer solution is transformed into a two-phase system in which a solidified polymer-rich phase forms the continuous membrane matrix and the polymer lean phase fills the pores. A detailed description of the phase inversion process is beyond the scope of this section as it was widely discussed in Chapters 1 and 2; nevertheless a short introduction of this process will be presented.

A homogenous polymer solution is cast as thin film and subsequently immersed into a non-solvent bath. The diffusional exchange of solvent and non-solvent brings the film solution into an instable state resulting in phase separation, either by liquid-liquid ( $l-l$ ) or by solid-liquid ( $s-l$ ) demixing, depending on the type of polymer and the precipitation conditions employed [76,77]. The following phase inversion processes can be distinguished: (i) precipitation from the vapor phase; (ii) precipitation by controlled evaporation; (iii) thermal precipitation; and (iv) immersion precipitation.

For amorphous polymer systems, liquid-liquid phase separation occurs by nucleation and growth of the polymer-lean phase when the film composition enters locally the metastable region between the binodal and the spinodal (unstable with respect to  $l-l$  demixing). The unstable polymer solution falls apart in a polymer-rich and a polymer-poor phase. The polymer-rich phase will form the matrix where the polymer-lean phase will form the pores. [78]. The (partial) phase inversion process performed can result in a variety of different cellular morphologies including open and closed sponge or finger-like pores. The (cellular) morphology depends strongly on the diffusion kinetics and thus on the rate of transfer of solvent and non-solvent [79,80]. For semicrystalline polymer systems, delayed conditions suppress  $l-l$  demixing and thus favors  $s-l$  demixing by allowing crystallization to take place.

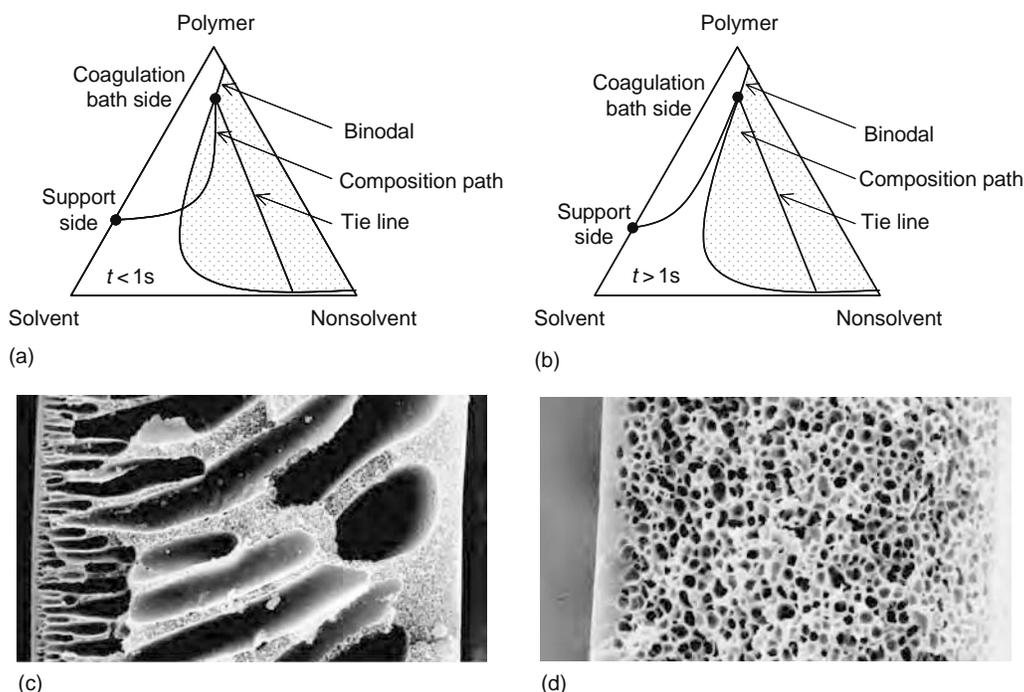

Ternary mass transfer models have been used to calculate the diffusion trajectories and the (polymer) concentration profiles within the film in the first stages of immersion [81–84]. Generally, two types of demixing are distinguished, namely *instantaneous* and *delayed* demixing with respect to  $l-l$  phase separation. Instantaneous  $l-l$  demixing occurs when the composition of the film falls immediately after immersion within the binodal envelope. This is normally the case when a (strong) non-solvent with a high affinity to the solvent is used in the coagulation bath (Figure 3.8a). The corresponding polymer concentration profile shows a steep increase near the film/bath interface leading to asymmetric open cellular membranes (Figure 3.8c) with typically a thin dense top layer (skin) and possibly macrovoids in the porous support layer [77,81].

If the demixing is delayed, compositional changes in the film will not be disrupted by phase separation. Desolvation can thus proceed for a longer time without triggering demixing (Figure 3.8b) resulting mainly in higher polymer concentration throughout the polymeric film. In this case, the polymer concentration profile within the film becomes less steep and more symmetric structures are obtained. Delayed demixing conditions generally suppress macrovoid formation and lead for amorphous polymer systems to the formation of a thick dense top layer (Figure 3.8d). Additional morphological fine-tuning has been performed by adjusting the temperature of the precipitation bath or by addition of a fourth component to the casting solution [82–84]. For microfiltration processes, the resulting membrane morphologies are far more regular and show higher permeabilities while retaining the required retention properties.

##### 3.4.1.2 Basic Membrane Modification

Most commercial microporous membranes are hydrophobic and relatively inert. If the selected basic membrane does not possess the functional groups necessary for spacers arms and ligand coupling, it can be activated to acquire reactive groups such as hydroxyl, carboxyl, halogen, or amine groups using similar methods as for particulate materials. The major methods employed to modify the porous membranes (some of them already mentioned) are based on

- *Coating Technique:* This technique usually deposits a hydrophilic layer such as HEC, polyvinyl alcohol, chitosan, polyacrolein, and polyethylenimine on a hydrophobic one [13,71,85,86]. The coating layers prepared are, however,

**FIGURE 3.8** Schematic representation of the composition path of the cast film immediately after immersion in the coagulation bath for (a) instantaneous and (b) delayed demixing systems, and the scanning electron microscope (SEM) picture of the resulting membranes (c) and (d).

not durable and stable and can be easily leached out. To overcome this drawback, the membranes (polyvinylidene fluoride, polyethersulfone polytetrafluoroethylene, polycarbonate, nylon, etc.) are coated with a mixture containing a functional monomer (hydroxyalkyl acrylate or methacrylate), a polymerization initiator (ammonium or potassium persulfate), and a cross-linking agent (difunctional acrylates, methacrylates, or acrylamides) and are exposed to radical polymerization initiated by heating UV or  $\gamma$ -radiation [72].

- *Grafting Polymerization*: A technique suitable for hydrophobic and inert microporous membranes such as polyethylene and polypropylene. The membranes can be grafted with monomers like sodium styrenesulfonates, vinyl acetate, 2-hydroxyethyl methacrylate to introduce various ion-exchange groups ( $-\text{NH}_2$ ,  $-\text{SO}_3\text{H}$ ,  $-\text{COOH}$ ) or with glycidyl methacrylate to acquire reactive epoxide groups that can be further modified with ionic-exchange groups, metal chelate groups, or hydrophobic groups (phenyl, butyl, phenylalanine, tryptophan) [45,87,88].
- *In Situ Copolymerization*: In situ copolymerization of two different monomers is often used for single step preparation of mechanical stable microporous membranes with functional groups. One of the monomers, such as vinylpyridine, acrylamide, vinyl alcohol, glycidyl methacrylate, and its derivative, serves as the core support material for functional groups. The second monomer (divinylbenzene, ethylene dimethacrylate, and methylene-bis-acrylamide) functions as a cross-linker and offers mechanical strength. Inorganic salts or organic solvents are usually used as porogen agents.
- *Other Methods*: Examples for other methods include co-casting of a hydrophobic and a hydrophilic polymer that contains amine, imine, hydroxyl, or carboxyl groups [61,89]; surface modification by oxidation with ozone or by exposure to an electron or ion-beam; ultrasonic etching; and UV or laser irradiation [90–92]. A variety of functional groups have been also introduced onto the membrane surfaces by applying the gas discharge techniques (plasma treatment) operated at low or ambient pressure [93,94].

However, the methods applied to obtain membranes with hydrophilic and chemically modifiable surfaces via physical or chemical posttreatment of hydrophobic membranes often result in unwanted and irreproducible inhomogeneities [95]. Thus the main limitation for supports in affinity separation presently encountered lies in the availability of membranes with functional groups suitable for ligand coupling. This imposes an increased need for the development of hydrophilic microfiltration membranes with suitable functionalizable groups.

### 3.4.2 PREPARATION OF MONOLITHIC STATIONARY PHASES

The monoliths are prepared both from organic (mainly based not only on polystyrene, acrylamides, acrylates, or methacrylates but also on imprinted polymers) and inorganic materials (based on silica, zirconia, titania, or aluminium oxide) as continuous

block interlaced with free dead-ends channels. They have similar advantages compared to membrane chromatography but their preparation differs from the classical membrane supports. The preparation of continuous beds can be generally divided in to: polymerization of an organic monomer in the presence of additives, formation of silica-based network via the so-called solgel process, and fusing the porous packing material inside the chromatographic column by a sintering process.

### 3.4.2.1 Preparation of Silica Monoliths

Until now few methods are reported for the preparation of silica monoliths. The extensively used solgel technology was introduced by Minakuchi et al. [73] and produced the first uniform porous silica column for reversed-phase chromatography. The method is based on hydrolytic polycondensation of alkoxy silicon derivatives (e.g., tetraethyl or tetramethyl orthosilicate) in aqueous media followed by phase separation in the presence of water-soluble organic polymers. The reaction occurs as follows: tetramethoxysilane (TMOS) is added to a polyethylene oxide (PEO) aqueous solution, in the presence of 0.01 N acetic acid as reaction catalyst. The resulting mixture is stirred at 0°C for 30 min and then poured into a polycarbonate mould where it is allowed to react at 40°C. Within 2 h of reaction the gelation occurs. The gelation process starts with polymer aggregation, followed by interpenetration of the formed clusters. Finally, the clusters link together to form the network. The gel is subsequently aged at the same temperature for a day to increase the stiffness and the strength of the silica network. The obtained silica rods are washed with water and aqueous ammonium hydroxide to adjust the mesopore structure and then cut to the desired length upon drying. The rods can be derivatized to C<sub>18</sub> phase by applying a toluene solution of octadecyldimethyl-(*N,N*-diethylamino)silane at 60°C, followed by trimethylsilylation with hexamethyldisilazane.

Several groups are nowadays involved in the preparation of silica monoliths using modified versions of the solgel technology proposed in 1996 by the Tanaka group. Research is carried out to improve the polycondensation starting material, different precursors such as TMOS, polyethoxydisiloxane, methyltriethoxysilane, aminopropyltriethoxysilane, 3-2-aminoethylaminopropyltriethoxysilane, or *N*-octyltriethoxysilane were investigated [96–100]. Numerous procedures concerning the reaction parameters are described in literature. It is commonly accepted that linear or randomly branched silica chains are formed under acid catalyses [101,102]. In contrast, under basic catalytic conditions a network of uniform particles with a large pore volume is formed [103,104]. The addition of additives such as polyethylene oxide or polyethylene glycol to the sol leads to the formation of silica monoliths of different morphologies and subsequently different properties [105,106].

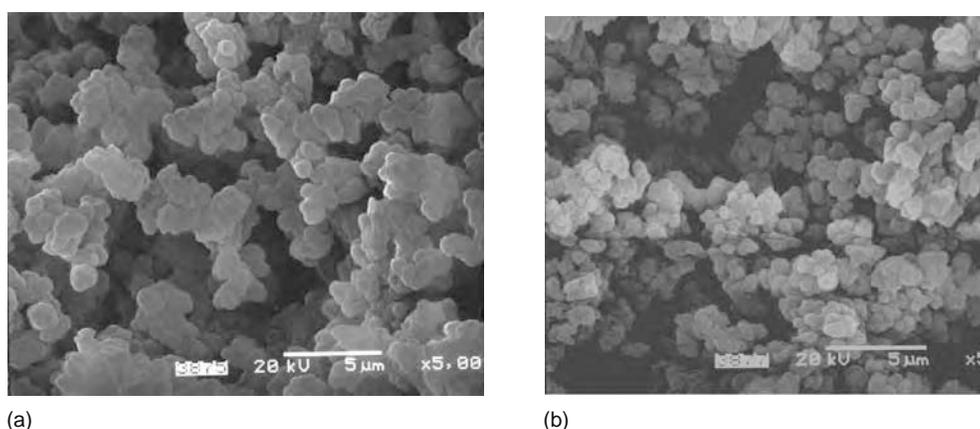

Various aging, drying, and cladding steps are also presented in literature. Gel drying is a critical step in silica monoliths preparation, which can cause large gel shrinkage and cracking. Therefore, besides classical drying at room temperature (with or without solvent exchange), many drying methods including the replacement of alcohol by washing with liquid CO<sub>2</sub> and drying above the critical point, replacement of alcohol by water followed by washing with acetone and liquid CO<sub>2</sub>, and supercritical drying at 35°C and 8.5 MPa have been investigated [107,108]. Despite the efforts in finding the most suitable drying methods, gel shrinkage may cause void spaces between the formed silica network and the column wall. A way to avoid these problems is encasing the resulting silica gel into a polytetrafluoroethylene tubing compressed under external pressure. A good review paper on the preparation of silica gel-based monoliths via solgel method has been recently published [109].

Another approach for the preparation of silica-based continuous beds belongs to Fields [74]. He synthesized a porous chromatographic support inside a silica tube by the following procedure: a fused silica column is filled with a 10 wt% solution of formamide in potassium silicate and placed in a 100°C gas chromatograph oven for 1 h. The column is then washed with water, 50/50 water/methanol, methanol, and tetrahydrofuran and purged with dry helium for 24 h at 120°C. Subsequently, the mixture is reacted with 10% dimethyloctadecylchlorosilane (ODS) in dry toluene for 5 h [110,111]. The morphology of the material was clearly inhomogeneous with a distribution of the mean pore diameter ranging from ~0.2 to ~3 μm. Nevertheless the prepared monoliths were used for separation of alkylbenzenes and polypeptides in reverse-phase chromatography with reasonable efficiency.

Embedding particulate material within a porous matrix may decrease the shrinking and cracking of the solgel prepared monoliths resulting in increased separation efficiency. Dulay et al. [112] produced particle-loaded monoliths by heating a tube filled with a mixture of TEOS and ODS particles in ethanol. Preparation of monoliths with entrapped silicate particles (coated with ODS or *L*-dansylphenylalanine imprinted polymers) was reported by Chirica and Remcho [113], resulting in faster and more efficient chromatographic media.

### 3.4.2.2 Preparation of Organic Polymer Monoliths

The preparation of polymeric monoliths is relatively simple compared with those of the silica rods. A polymerization mixture consisting of monomer, cross-linker, initiator, and porogenic solvent is introduced into a sealed tube. The reaction can be temperature or redox initiated and in the case of transparent molds UV light can also be used to trigger the polymerization. At the end of the reaction the seals are removed and the tubes are attached to a pump, which flushes solvent through the monolith to remove the porogens and the unreacted components. The obtained monolith can be radial or axial compressed to prevent the formation of voids and further functionalized for different chromatographic modes. The majority of current monolithic supports

**FIGURE 3.9** SEM picture of monoliths prepared from (a) polystyrene-divinylbenzene and (b) methylmethacrylate. (Courtesy BIA Separations, Ljubljana, Slovenia.)

used in chromatographic processes recently reviewed in Refs. [56,114–116] are based on polystyrene-divinylbenzene, polyacrylamides, polyacrylates, and polymethacrylates (Figure 3.9a). The reader should realize that there is a very large class of monomers with different functionalities, which can be used in the preparation of continuous beds. Multifunctional oligomers or polymers including derivatives of cyclodextrins and proteins (acting simultaneous as cross-linkers and chiral selectors) have recently been used in monoliths preparation [117,118].

#### 3.4.2.2.1 Preparation of Polystyrene-Based Monoliths

The commonly used monomers in the preparation of polystyrene (PS)-based monolithic columns are styrene and 4-chloromethylstyrene while divinylbenzene (DVB) is usually the cross-linker. The PS-DVB continuous beds were introduced by Svec and Fréchet [119] in the early 1990 as protein separation media. They were prepared by free radical polymerization of styrene and divinylbenzene in the presence of dodecylalcohol as pore-forming agent and 2,2'-azo-bis-isobutyronitrile (AIBN) as initiator. The polymerization mixture was reacted inside the mold at 70°C for 24 h. Due to its highly hydrophobic nature, the prepared continuous bed can be directly used in reverse-phase or precipitation-redissolution chromatography [120,121]. To increase chromatographic interactions, the monolithic surface can be modified by including an alkylstyrene monomer in the polymerization mixture. The modification can also be achieved by introducing functional groups onto the polymeric surface after monolith formation using, for example, a strong Friedel–Craft catalyst (aluminium chloride) and an alkyl halide (chlorooctadecane) in nitrobenzene [114].

Hydrophilic polystyrene-based continuous beds bearing a hydrophilic surface on a hydrophobic polymeric support were prepared by a two-step modification of polychloromethylstyrene monolith first with ethylenediamine followed either by a reaction with  $\gamma$ -gluconolactone or with chloroacetic acid [57,122]. Activation could also be performed by grafting 4-vinyl-2,2-dimethylazactone onto the monolith porous surface [123].

#### 3.4.2.2.2 Preparation of Polyacrylamide Monoliths

Hjerten et al. [124] introduced the monolithic stationary phases based on acrylamides in the late 1980s. The cross-linked polyacrylamide can be directly synthesized within the mold by a one step free-radical chain polymerization. Acrylamide, methacrylamide, or piperazine diacrylamide are often employed as monomers, while *N,N'*-methylene-bis-acrylamide is used as a cross-linker. 2-acrylamido-2-methylpropane sulphonic acid, vinylsulphonic acid, butyl methacrylate, or stearyl methacrylate are usually added to the polymerization mixture to provide charge and functional groups [114].

Xie et al. [42] prepared rigid porous polyacrylamide-*co*-butylmethacrylate-*co*-*N,N'*-methylene-bis-acrylamide monolithic columns with controlled hydrophobicity for chromatographic separation of proteins. They also prepared porous hydrophilic polyacrylamide-*co*-*N,N'*-methylene-bis-acrylamide monolithic rods using alcohols with different carbon chain lengths (from methanol to decanol) as pore-forming agents [125].

#### 3.4.2.2.3 Preparation of Polymethacrylate-Based Monoliths

Continuous beds prepared from acrylates and methacrylates were introduced as chromatographic media in the early 1990s by Svec and Fréchet [126]. The polymerization mixture generally consists of a mixture of monomers including glycidyl methacrylate (GMA), diethyleneglycidyl methacrylate (DEGMA), 2-hydroxyethyl methacrylate, ethylene dimethacrylate (EDMA, which can also act as a cross-linker), and other methacrylate-esters, one or more porogenic solvent (such as methanol, propanol, cyclohexanol, isooctane, dodecanol, toluene, dioxane, acetone, or acetonitrile) and a radical initiator (usually AIBN) temperature or UV light activated. The monoliths morphology with well-defined bimodal pore size distribution (Figure 3.9b)

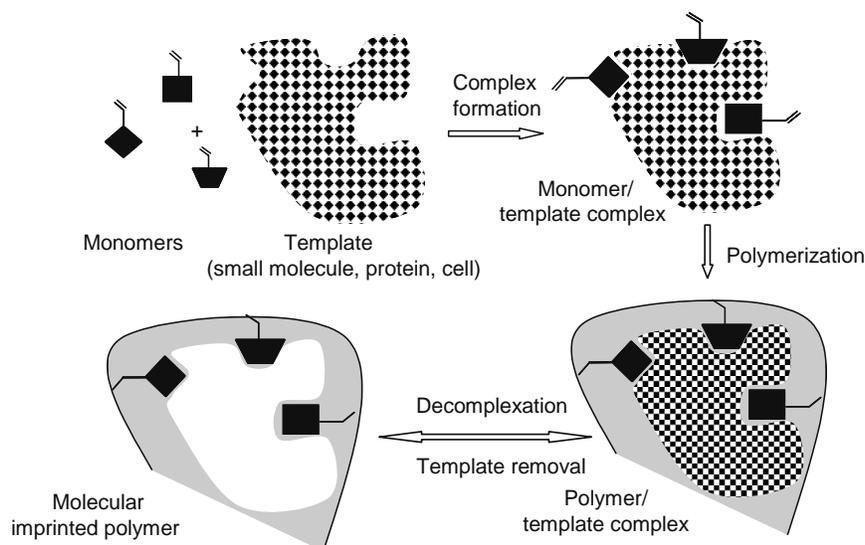

FIGURE 3.10 Principle of molecular imprinting technique.

can be adjusted by varying the percentage of cross-linking monomer, the type and quantity of porogenic agents as well as the ratio between the monomer and the porogen phase.

Poly(glycidyl methacrylate-*co*-ethylene dimethacrylate) is a material most often used in the preparation of monolithic rods, since it possesses reactive groups that allow for easy functionalization. Preparation of poly(GMA-*co*-EDMA)-based monoliths bearing functional amino groups via a diethylamine reaction was reported by Svec et al. [127]. Viklund et al. [128] reported a photo-initiated in situ polymerization method for the preparation of monolithic stationary phases containing sulfonic acid group by grafting poly(2-acrylamido-2-methyl-1-propanesulfonic acid) onto the internal surface of hydrolyzed poly(GMA-*co*-EDMA) monoliths. A  $^{60}\text{Co}$   $\gamma$ -radiation-induced copolymerization of DEGMA and GMA monomers using different porogenic agents (including alcohols, acetone, THF, and dioxane) was recently proposed by Grasselli et al. [129] to prepare monolithic columns with adjustable morphologies.

Although the preparation of continuous beds on a small scale is easy, the preparation of large-size monoliths is quite difficult. The unstirred nature of the polymerization within the mold leads to a low capacity to effectively dissipate the exothermic reaction heat. The appearance of radial temperature gradient across the reaction mixture also results in the formation of inhomogeneities in the pore structure of the obtained monolith. This is the reason why most of the work reported in the last decades focused on the application of small-size monoliths in chromatographic processes.

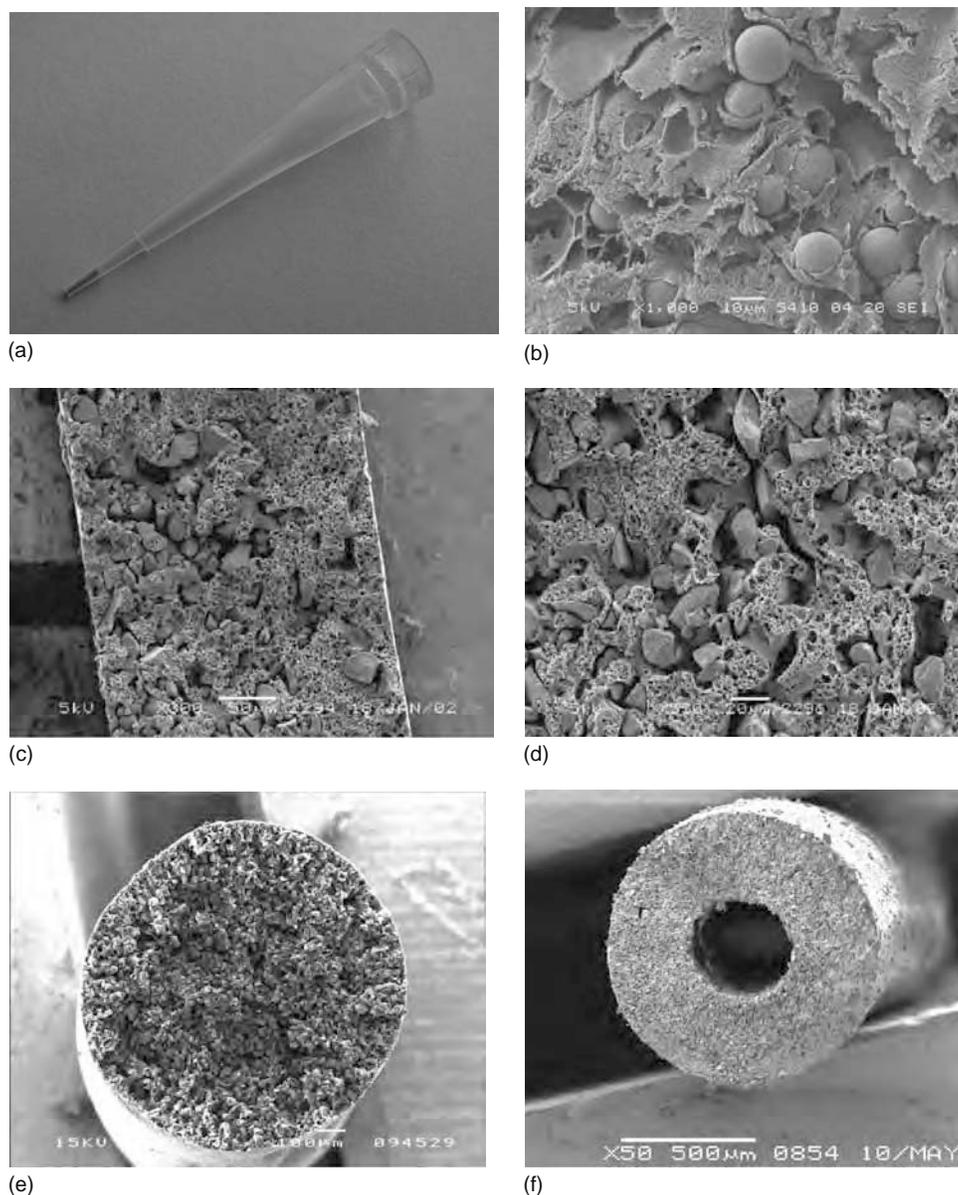

#### 3.4.2.2.4 Preparation of Monolithic Molecularly Imprinted Polymers

Molecular imprinting technique was recently used to prepare highly selective tailor-made synthetic affinity media used mainly in chromatographic resolution of racemates or artificial antibodies [130–133]. A complex between the template molecule and the functional monomer is first formed in solution by covalent or non-covalent interactions (Figure 3.10). Subsequently, the three-dimensional architecture of these complexes is confined by polymerization with a high concentration of cross-linker. The template molecules are then extracted from the polymer leaving behind complementary sites (both in shape and functionality) to the imprinted molecules. These sites can further rebind other print molecules.

Matsui et al. [134] first reported the preparation of molecularly imprinted monoliths based on functional monomer such as methacrylic acid or 2-trifluoromethyl-acrylic acid via in situ polymerization. The reaction mixture consisting of monomer, cross-linker (ethylene glycol dimethacrylate), porogenic solvents (cyclohexanol and 1-dodecanol), initiator, and template molecule was degassed and poured into a column where the polymerization took place. When the reaction was completed, the template molecule and the porogenic solvents were extracted with methanol and acetic acid resulting in monoliths with molecular recognition in the separation of positional isomers of diamionaphthalene and phenylalanine anilide enantiomers.

### 3.4.3 PREPARATION OF PARTICLE-LOADED MEMBRANES

Nowadays, methods are known for the preparation of porous polymeric supports comprising particulate material from an appropriate mixture of starting components. Such a material prepared by a casting process is limited in its three dimensional size by the housing it is cast into (Zip Tip, Millipore, Figure 3.11a and 3.11b) or is in the form of a sheet (Empore; Acti-Mod, FMC Bioproducts; Biorex, Bio-Rad) [16,17].

**FIGURE 3.11** Particle-loaded membrane adsorbers in different geometries (a) zip-tip millipore adsorber, (b) zip-tip adsorber, higher magnification, (c) flat membrane, (d) flat membrane, higher magnification, (e) full fiber, and (f) hollow fiber.

The available preparation routes for porous polymeric fibers with particulate material incorporated require an additional process steps to introduce the desired porosity [135]. After the preparation of the matrix comprising particulate material, either the particulate material is removed from the nonporous fiber or the nonporous fiber is stretched resulting in porous fibers. In the latter case, a microporous fiber comprising particles having a certain sorptive function can be obtained. Depending on the actual process steps needed to come to the final product, suitable starting materials with properties that can sustain the conditions of the additional process steps have to be selected. Obviously, such a requirement limits the type of polymeric material that can be used. Furthermore it puts limitations on the type of particulate material that can be comprised in the polymeric matrix. A very high degree of particle loading will reduce the mechanical strength of the mixed matrix and therefore restrict the stretching procedure. The force required to reach sufficient stretching of the matrix material limits the degree of loading. By stretching the particle comprising material the particulate material can drop out of the porous structure to be formed. In processes involving melt extrusion, only particulate material that can sustain temperatures required to melt the matrix polymer, usually above 200°C [18], can be applied.

Disadvantages of the known porous polymeric membrane preparation processes are that they involve additional process steps after the formation of the fiber to come to a final product. It is therefore desirable to have a more efficient preparation process. A new method to prepare structures of any geometry (Figure 3.11c through 3.11f) and large variety of functionality

was recently proposed [52]. The authors proposed to incorporate the functionality by dispersion of particles in a polymeric porous structure formed by phase inversion. A slurry of dissolved polymer and particulate material can be cast as a flat film or spun into a fiber and can then be solidified by a phase inversion process. This concept is nowadays commercialized by Mosaic Systems. The adsorber membranes prepared via this route contain particles tightly held together within a polymeric matrix of different shapes, which can be operated either in stack of microporous flat membranes or as a bundle of solid or hollow fiber membranes.

These membranes may also serve as a platform to which an end-user can couple the specific ligate needed. This has been recently pointed out by Klein [10] as one of the significant opportunities in membrane chromatography. The reader may note that the function of polymer binder is to be highly porous, having a high degree of pore interconnectivity as well as having a low-adsorption tendency toward the desired products. By choosing the particles and the binder one can establish various functions such as ion exchange, adsorption, catalysis, and hybrid such as reactive chromatography.

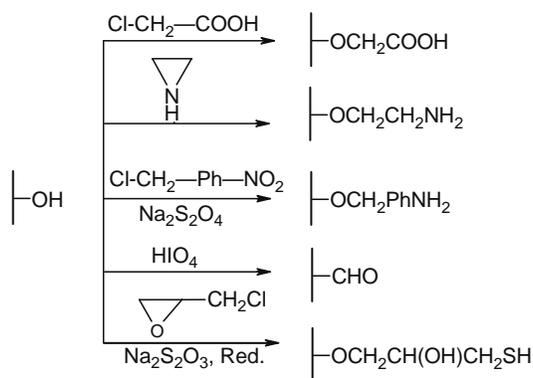

### 3.4.4 MEMBRANE ACTIVATION AND LIGAND COUPLING

The spacer arms and the affinity ligand molecules may be directly or indirectly linked to residual functional groups of the membrane by any procedure that retains the mechanical and hydraulic membrane properties while substantially retaining the binding activity of the affinity ligand. The monolithic stationary phases used in affinity chromatography are typically prepared by ligand immobilization onto the in situ polymerized support. Nevertheless, methods in which the ligand is attached to one of the comonomers were also reported [136]. In the following section, the reactions widely used for membrane activation and ligand coupling and extensively reviewed in recent literature are discussed separately for different types of functional groups containing polymers (Table 3.1).

1. Polymers containing hydroxyl groups including polysaccharide, polyvinyl alcohol and its copolymers, polyhydroxyethyl methacrylate, silica, and porous glass can be used as material supports not only for direct ligand coupling via, e.g., cyanogen bromide, triazine, or cyclic carbonate reaction, but also for modification reactions leading to other reactive functional groups such as carboxyl, carbonyl, and mercapto groups (Figure 3.12) [137].
  - *Cyanogen Bromide Reaction* (Figure 3.13a): This reaction was introduced by Axen et al. [138] in late 1960s and became one of the most extensively used coupling method. The hydroxyl-containing polymer is activated with cyanogen bromide at pH 10–11.5. Compounds containing free amino groups can be attached covalently to the activated polymer at mild alkaline pH values. The cyanogen bromide activation reaction is considered to proceed via the 2,3-*trans*-imidocarbonate intermediate, leading to the formation of three possible types of bonds with protein amino groups: N-substituted imidocarbonate, N-substituted carbamate, and N-substituted isoureas. The cyanogen bromide method was used for immobilization of different proteins on cellulose, agarose, dextran, and copolymers of hydroxyethyl methacrylate with acrylamide [139–142].
  - *Cyclic trans-2,3-Carbonate Method*: This method was first used for immobilization of different biomolecules on cellulosic materials [143]. The reaction of cellulose with ethyl chloroformate in anhydrous organic solvents gives

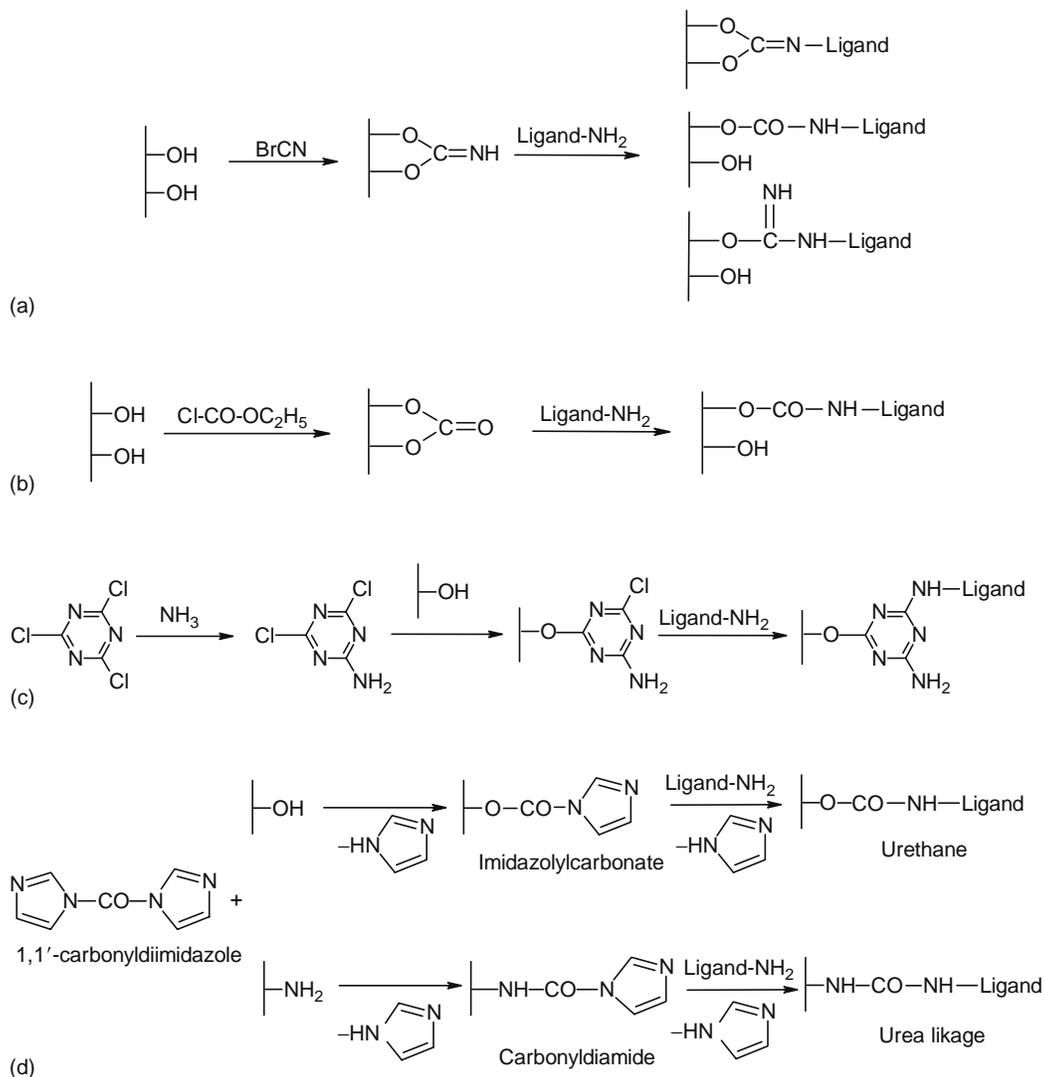

**TABLE 3.1**  
**Modification Reactions with Polymers Containing Different Functional Groups**

Functional Groups	Material Type	Modification	References
Hydroxyl	Polysaccharides (cellulose, agarose, dextran, chitin, chitosan), inorganic glass, polyvinylalcohol, polyhydroxyethyl methacrylate	Cyanogen bromide, triazine method, cyclic <i>trans</i> -2,3-carbonate reaction, carbonylation, periodate oxidation, epoxide activation	[137–150]
Carboxyl	Poly(acrylic acid), poly(glutamic acid), CM-cellulose, poly(acryl amide)	Curtis azide rearrangement, coupling reagent method, acid anhydride reaction	[151–154]
Aldehyde and acetal	Polymers reacted with glutaraldehyde, polysaccharides reacted with periodate	Schiff base formation reaction	[137,155,156]
Amide	Polypeptides and polyamides such as nylon	Peptide amide bond cleavage, <i>N</i> -alkylation of the amide bonds, imidoester reaction	[137,151]
Amino	Aminoethylated polysaccharides and silica, arylaminated polysaccharides, poly-( <i>p</i> -aminostyrene), synthetic polymers	Carbamylation and thiocarbamylation method, diazotization, the four-component condensation reaction, glutaraldehyde treatment	[155,157–161]
Mercapto	Glutathione-agarose, thiolated agarose, Enzacryl polythiol	Treatment with dipyridyldisulfide, carbodiimide activation, thiol-disulfide interchange reactions	[137,153,154,162,163]

**FIGURE 3.12** Coupling reactions for ligands immobilization on polymers containing hydroxyl groups.

cyclic *trans*-2,3-carbonate derivative of cellulose (Figure 3.13b). The *trans*-2,3-carbonate group is analogous to the cyclic *trans*-2,3-imidocarbonate structure, which is assumed to be the intermediate reactive in cyanogen bromide activation. Nucleophilic attack on the cyclic carbonate by a ligand containing amino group leads to ring opening and the formation of N-substituted carbonates.

**FIGURE 3.13** Schematic representation of (a) cyanogen bromide reaction, (b) cyclic *trans*-2,3-carbonate activation method, (c) triazine activation method, and (d) carbonylation reaction.

- *Triazine Method* (Figure 3.13c): The method was used mainly for polysaccharides including cellulose, agarose or cross-linked dextran, and vinyl alcohol supports [144,145]. Dichloro-*s*-triazinyl derivatives that react rapidly with protein are prepared by reaction with 2,4,6-trichloro-*s*-triazine (cyanuric chloride) at room temperature. The temperature may be raised to accelerate the reaction. The remaining chlorines may be treated with an amine to prevent further reaction, including polymer cross-linking. As the reaction of the second chlorine with protein is very fast, it is preferable to replace the second chlorine and use the third chlorine for the coupling reaction. Monochloro-*s*-triazinyl derivatives can be prepared by allowing the polymer to react initially with cyanuric chloride followed by a reaction with a low molecular weight amine under controlled conditions to leave the third chlorine unreacted. It is, however, preferable to use 4,6-dichloro-*s*-triazine derivative, 2-amino-4,6-dichloro-*s*-triazine, or the so-called Procion M dyes.
  - *Carbonylation* with carbonyldiimidazoles or carbonylditriazoles to form the corresponding carbonate esters can be easily performed in the presence of sodium alcoholates catalyst on hydroxyl containing polymers [146,147]. The resulting iminocarbonate ester can react further with amines forming stable urethane linkage between the hydroxylic support and the amino containing ligand (Figure 3.13d). If the support material contains amine groups instead of hydroxyl groups, the first intermediate formed is a carbonyldiamide, which can easily react with nucleophilic groups of the ligand [148].
  - *Periodate Oxidation* mainly of polysaccharide supports has become a popular activation technique for protein immobilization [149]. Sodium periodate ( $\text{NaIO}_4$ ) can react with vicinal *cis*-hydroxyl groups on cellulose, dextran, or any other diols to produce aldehyde groups. These aldehyde groups can easily be transformed into secondary amines by reductive oxidation or to hydrazides by reaction with dihydrazine. Further attachment of ligands or spacer molecules can be performed via primary amino groups.
  - *Epoxide Activation* using bioiranes (such as 1,4-butanediol dicyclydyl ether), epichlorhydrine, or epoxy bromopropane is also intensively described in literature [150]. The epoxide groups can react with nucleophilic reagents including  $-\text{OH}$  and  $-\text{NH}_2$  by ring opening. Condensation of the first ring with hydroxyl groups can be catalyzed at pH 11 while coupling amine or thiol groups with the second ring takes place at a lower pH value. Simultaneously hydrogel cross-linking may occur.  $\text{NaBH}_4$  can be added to the reaction mixture to prevent the oxidation of the di-epoxides.
2. Polymers containing carboxyl groups activated as acylazide, acid anhydride, or active ester by condensation reagents and four-centered reaction can be used for ligand immobilization employing various coupling reactions via amino groups of the protein to form an amide bond (Figure 3.14) [151]. Polyacrylic acid and polymethacrylic acid are typical polymers used for these activations. They can be applied as homopolymer or copolymers with acrylamide.
- *Curtis Azide Rearrangement*: The polymer containing carboxyl groups is modified to a methyl ester, which reacts further with hydrazine hydrate to form a hydrazide derivative. The hydrazide subsequently reacts with an aqueous sodium nitrate solution to give an azide derivative, which can react with a ligand amino group under mild alkaline conditions (Figure 3.14a) [152].

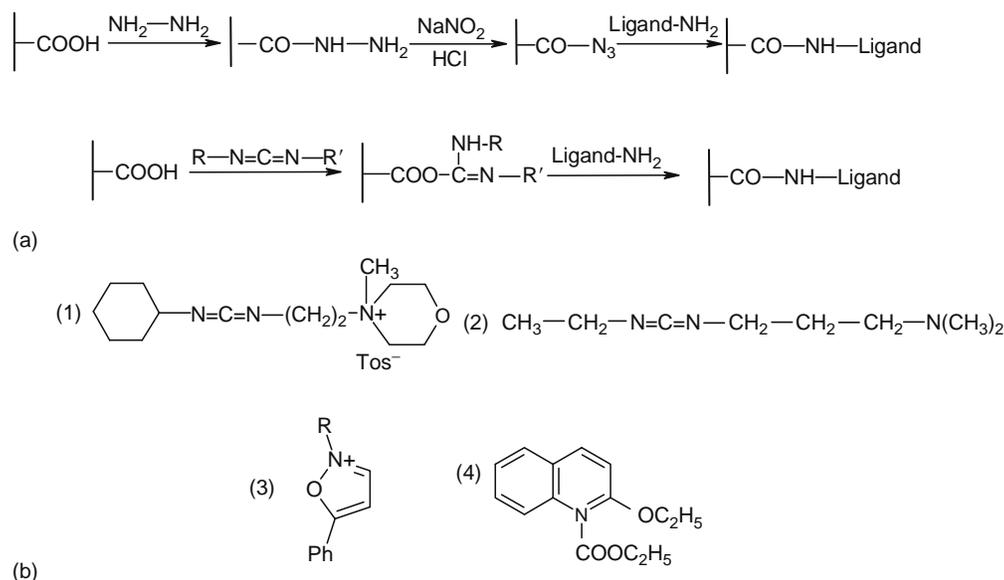

FIGURE 3.14 Schematic representation of (a) Curtis azide activation and (b) coupling reagents activation method.

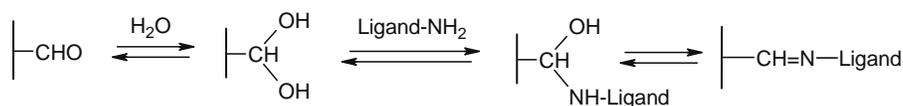

FIGURE 3.15 Coupling reactions for ligands immobilization on polymers containing aldehyde groups.

- Coupling Reagents Method:** This method involves water-soluble carbodiimides and similar coupling reagents that react with carboxyl groups of the polymer at room temperature and slightly acidic pH values (pH 4–5) to give *O*-acyl isourea derivatives. These highly reactive intermediates either condense with amines to yield the corresponding amides or rearrange to an acyl urea. The most widely used water-soluble carbodiimides for the activation of carboxyl groups are 1-cyclohexyl-3,2-(4-*N*-methylmorpholinium) ethyl carbodiimide tosylate (1) and 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (2). Other coupling reagents *N*-alkyl-5-phenylisoxazolium salt (3) and *N*-ethoxy carbonyl-2-ethoxy-1,2-dihydro-quinoline (4) can be used in a similar manner (Figure 3.14b) [153,154].
- Widely used as polymeric supports for protein immobilization are the polymers containing aldehyde and acetal functional groups (Figure 3.15) [155].

    - Schiff Base Formation Reaction:** This reaction (especially the glutaraldehyde reaction) is an inexpensive and easy to use method extensively used for the immobilization of various ligands (such as proteins, enzymes, and cells), on amine, amide, or hydroxyl-containing support materials [49,156]. At low pH in dilute solution, glutaraldehyde (GA) is present as monomer in its free aldehyde form, as hydrate or hemiacetal, while at higher concentrations it polymerizes into oligomeric hemiacetals. All of these species can react with proteins and lead to immobilization. Activation of the support is often conducted at low pH to catalyze acetal formation, while the coupling of the biomolecule is carried out at elevated pH to promote the nucleophilic attack onto the carbonyl group improving thus the immobilization yield.
  - Polymers containing amino groups are used as support materials in chromatographic separation processes using various coupling methods. The amine groups can be activated using, for example, glutaraldehyde and cyanuric chloride reaction. They can also be modified by phosgene and thiophosgene to isocyanate and thioisocyanate groups, respectively. The newly formed functional groups can react with the ligand amino groups (Figure 3.16). The carboxyl groups of the bioligands can also be directly coupled onto polymers containing amino groups using carbodiimide or similar coupling reactions to form stable amide bonds.

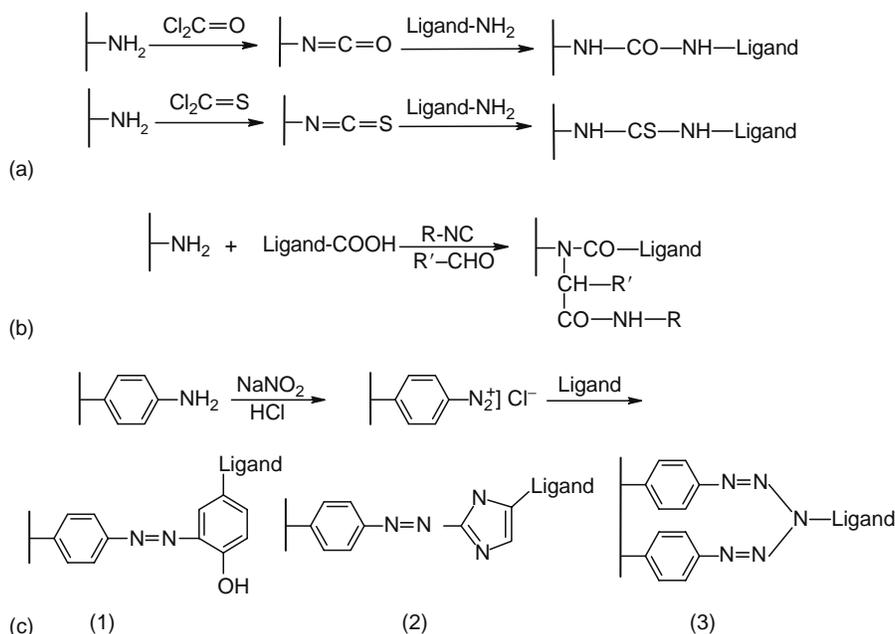

FIGURE 3.16 Schematic representation of (a) carbamylation and thiocarbamylation reactions, (b) four-component condensation reaction, and (c) diazotization activation.

- *Carbamylation and Thiocarbamylation Reactions* (Figure 3.16a): These reactions have been widely used for protein immobilization on many polymers, including polyisocyanate and polyisothiocyanate styrene and on other copolymers containing these styrene units and isocyanate or isothiocyanate groups [157,158].
  - *The Four-Component Condensation Reaction*: The reaction combines the carboxyl and amino groups to form an amide bond in an aqueous medium at neutral pH (Figure 3.16b) and allow for considerable versatility and high selectivity. This reaction can be used for carboxyl and amine-containing polymers [159].
  - *The Diazotization Reaction*: This reaction can be applied for different proteins coupling to polymers containing arylamino functional groups [160,161]. The polymers are reacted with nitrous acid to form aryl diazonium functional groups. The electrophilic aryl diazonium ion mainly attacks activated aromatic rings, such as phenols of tyrosine or imidazole of histidine to form the corresponding azo derivatives. Tyrosine and histidine react at mild alkaline pH values (8–9) at comparable rates to form monoazo derivatives (1, 2) (Figure 3.16c). Amino groups ( $\alpha$ -amines and the  $\epsilon$ -amino groups of lysine) react under similar conditions with 2 moles of diazonium salt to give the disubstituted bis-azo derivatives known as triazenes (3).
5. Polymers with other functional groups including polymers possessing amide bonds, polyacrylamide and polyamides are useful hydrophilic and electrically neutral supports for ligand coupling. Polymers containing mercapto functional groups, such as glutathione-agarose or thiolated-agarose [162,163], were used for specific reversible coupling to protein mercapto groups (cystein) via thiol-disulfide interchanging reactions. Polyacrylamide supports can be chemically modified by reacting with hydrazine or ethylenediamine to obtain the corresponding acyl hydrazide or aminoethyl derivatives. Polymers containing 3-fluoro-4,6-dinitrophenyl groups, such as poly(methacrylic acid-*co*-methacrylic acid 3-fluoro-4,6-dinitroanilide) or poly(methacrylic acid-*co*-methacrylic acid 3-fluoro-4,6-dinitrostyrene), can be used for ligand coupling via arylation with the amino groups of different biomolecules [151].

Very often used in various applications are the monoliths whose preparation routes involve chemical modifications with ethylenediamine, diethylamine or periodate, as well as grafting of monolithic pore surface via attachment of glucose, polyvinyl alcohol, dextran, ethyl cellulose, or 1,3-di-trimethylolpropane [122,128,164–167].

In case of proteins or enzymes as bioligand in the affinity separation processes, all the available information on amino acid composition, effects of specific chemical modifications on activity, or three-dimensional structure of the protein should be considered in selecting appropriate coupling reaction and functionalized polymer. The types of functional groups through which the covalent bond between the ligand and the polymeric support is formed should be nonessential for the biological activity of the biomolecule. Moreover, binding reactions that can be carried out under mild conditions and especially the reactions in aqueous media are preferred.

### 3.4.5 AFFINITY LIGANDS

In general, affinity binding between a ligand and a protein is more complex than protein adsorption on a plain surface. The ligands normally are positioned at a small distance from the solid surface and are able to form a sterical contact with the biomolecule. The ligands may also possess various functional groups that bind with the protein molecules through different types of interaction [168]. Depending on the product to be isolated the ligands can be, for instance a hormone, an inhibitor, an antigen, a specific-binding protein, or a cofactor, specifically chosen for an affinity adsorption process [10]. A brief list of ligands and their corresponding ligates are presented in Table 3.2.

The ligand molecules can be divided into two groups [12]: (i) specific ligands, which show specificity for only one complementary biomolecule; and (ii) group ligands that are based on biological recognition parameters but, which are not targeted to a very specific conformation or sequence of the ligate. A group-specific ligand may be a large macromolecule such as lectin, protein A, or protein G. They may also be small coenzymes such as adenosine monophosphate (AMP) or adenosine triphosphate (ATP), and nicotinamide-adenine dinucleotide (NAD) or nicotinamide-adenine dinucleotide phosphate (NADP). A large number of metabolic toxins such as free fatty acids, endotoxins of gram-negative bacteria, mercaptans as well as medications like nortriptyline, amitriptyline, diazepam, bromazepam bind preferentially to the albumin fraction of blood plasma.

Affinity ligands can also be classified into biospecific and pseudo-biospecific ligands. The biospecific ligands, although possessing high specificity with proteins, have certain deficiencies such as high cost, low stability for potential large-scale application and difficulties in immobilization. Nevertheless, a large number of such substances including various enzymes, protein A and protein G isolated antibodies, receptors or inhibitors have so far been investigated in affinity applications [8,12,169]. Ligands with pseudo-biospecific affinity have been recently employed in membrane chromatography. They can be distinguished by biological (amino acids, specially histidine, lysine, tryptophan) or nonbiological molecules (hydrophobic side chains, triazine dyes, metal ions). Immuno-adsorbers based on polyvinyl alcohol materials containing phenylalanine or tryptophan have been used for rheumatism and myasthenia gravis therapy [170]. Phenylalanine has been used as a ligand

**TABLE 3.2**  
**List of Ligands and Their Corresponding Ligates**

Ligand	Ligate
Dyes (Cibacron blue, red, active red, Procion yellow, Procion blue)	Various enzymes, lysozyme, catalase, phosphatase, malate/formate dehydrogenase, adenylase kinase, pyruvate decarboxylase, alkaline phosphatase, serum albumin, lipoprotein, interferon, growth factor, polypeptide hormone
Amino acids (Trp, Arg, Lys, His, Phe)	DNA, RNA, $\gamma$ -globulin, proteinase, carboxypeptidase, endotoxins, pyrogen, IgG, trypsin inhibitor, transferrin, casein, L-benzoyl arginine ethyl ester, cytochrome C
Peptides (pentadecapeptide, hexadecapeptide, poly-L-lysine)	IgG, heparin
Organic acids (oxaloacetic, citric, isocitric, pirivic)	Enzymes (malate dehydrogenase, lactate dehydrogenase, isocitrate dehydrogenase, citrate lyase)
Protein A/G, protein L, recombinant protein A/G, Concanavalin A, Annexin, Bradykinin	IgA, IgG, IgM, insuline-like growth factor, antibody, $\gamma$ -globulin, recombinant human IgGs, glucose oxidase, glycoproteins
IgG, IgM, IgE	Protein A, protein G, anti-IgE antibody
Metal chelates	Various histidine-, tryptophan-, cysteine-containing proteins, BSA, HSA, $\gamma$ -globuline, liver catalase, IgG, Concanavalin A, ovalbumin, lysozyme, histidine/tryptophan, cytochrom c, ribonuclease A, chymotrypsinogen A
Enzyme cofactor and inhibitors	Enzymes
Antibody/antigen	Antigen/antibody
Hormone	Receptor

for the purification of serum proteins and enzymes [171]. The compact porous separation units with immobilized histidine were applied in immunoglobulin G isolation [172]. Anion exchange membranes with immobilized histidine have also been used for removal of endotoxins from protein mixtures [173].

Affinity chromatography using immobilized metal ions (IMAC) is a highly efficient and flexible method for protein fractionating. The immobilized metal ligand has high affinity for a group of proteins whose exposed surface contains histidine, cysteine, or tryptophan amino acid residues. Iminodiacetic acid (IDA), a widely used metal-chelating ligand, can be bound to membranes or disks including agarose or poly(vinyl alcohol) matrixes, in a way similar to the silicagel or polymeric beads chemistry. The ions most efficiently chelated by the IDA, such as  $\text{Cu}^{2+}$ ,  $\text{Ni}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Co}^{2+}$ , and  $\text{Fe}^{2+}$ , are able to interact with histidine residues of various proteins. The resulting molecules can be specifically recognized and bound by IMAC allowing fast isolation from complex mixtures [2,174]. Few detailed reviews of these applications have recently been published [175,176].

Immobilized dyes have been found to act as pseudo-affinity ligands for a large number of biological molecules. The dyes are chemically stable, relatively inexpensive and have binding coefficients in the range needed for ready elution of ligates. Triazine-linked dyes have been used to mimic coenzymes that bind a number of dehydrogenases, hexokinases, alkaline phosphatase, ribonuclease, and carboxypeptidase. The Cibacron blue was used for the purification of microbial or plasma proteins and various proteins from yeast extracts [177]. The Procion blue binding of albumin is a well-known method for purifying proteins from contaminating transferrin, or a protein of similar physico/chemical properties that often contaminate albumin. Immobilized Cibacron Blue F3GA has been used for the purification of over 80 enzymes and proteins [8].

Combinatorial synthetic ligands (derived from a combinatorial library) started to be recently investigated in membrane chromatography for purification of valuable therapeutic proteins including human insulin precursor or immunoglobulin G [178,179]. Combinatorial peptides also proved to be suitable for immobilization on monoliths. Amatschek et al. [180] prepared continuous beds bearing newly designed combinatorial octapeptides for affinity separation of FVIII with good performances. Synthetic pentadecapeptides, hexadecapeptides, and nonapeptide hormone bradykinin immobilized on monolithic supports were investigated by Platonova et al. [181] for the purification of nonspecific polyclonal antibodies.

The affinity ligands may be directly or indirectly linked to residual functional groups of the matrix membrane by any procedure that substantially retains the mechanical and hydraulic properties of the membrane while substantially retaining the binding activity of the affinity ligand. The degree of ligand attachment to the activated sites is dependent on the ligand–ligand and ligand–activator interactions, charge and steric effects, the nature of the matrix material, as well as number of activated functional groups available for ligand coupling. An excessive number of ligands coupled to the support surface has to be avoided because this may otherwise lead to crowding and interferes with ligate recovery.

### 3.4.6 SPACER MOLECULES

Ligand–ligate complexes able to form in solution may not be able to form when one of the components is immobilized on a porous support. The interference may derive from the nearby support material itself or from other adsorbed proteins (especially

if the support participates in nonspecific bonding). Complex formation is inhibited because the ligate and ligand must compete with other proteins for the restricted space available adjacent to the immobilizing polymer. Impaired diffusion of the ligate to the ligand site due to the channel size or tortuosity may also cause interferences with the complex formation and the requirements for spatial orientation may not be achievable [8].

The employment of a spacer molecule facilitates molecular interactions between immobilized ligands and the targeted molecules. Relatively short aliphatic chains (4–10 carbon atoms in length) are ineffective for interactions involving one or more macromolecules, but longer aliphatic chains can alter undesirable hydrophobicity of the membrane surface. The length of the spacer molecule is often experimentally determined. Free hydroxyl groups of a polysaccharide or vinyl alcohol copolymer support can be linked to a protein ligand via a bifunctional spacer containing at least one terminal primary amino or hydrazido functional group. The remaining terminal group of the spacer can react with free amino or carboxyl functions of the ligand, or with free hydroxyl groups of a glycoprotein ligand. Convenient spacer molecules for these applications include diamine and dihydrazides such as C<sub>1</sub>–C<sub>6</sub>-alkyldiamines and C<sub>1</sub>–C<sub>6</sub>-dihydrazides, and β-alanine hydrazide, which provide free amino and hydrazido groups for reaction with the ligand. They can also be C<sub>4</sub>–C<sub>6</sub>-alkylamino acids, which provide free carboxyl groups.

The immobilization of different enzymes via a spacer molecule such as 6-aminocaproic acid yielded kinetic and structural characteristics similar to the free enzyme while providing increased stability and reusability. Triazine dyes (Cibacron Blue F3GA or one of the Procions) were coupled using polyethyleneimine (PEI) as a spacer to nylon membranes and their adsorption capacities for lysozyme, bovine serum albumin, malate dehydrogenase, or glucose-6-phosphate dehydrogenase were investigated. The use of long spacer molecules proved to reduce the steric interference allowing for multiple layering of large macromolecules at the membrane surface. Polyethylene glycol with a suitable chain length, generally between 50 and 250 carbon atoms, can be covalently coupled to the membrane surface through its amino groups by a proper immobilization method. The advantages of polyethylene glycol as a spacer molecule are its hydrophilic nature and biological inertness, quite beneficial in a device that contacts blood or plasma.

### 3.5 ADVANTAGES OF MEMBRANE CHROMATOGRAPHY

In chromatographic separations based on membranes, compact porous disks, tubes or rods, the ligate–ligand interaction takes place predominantly in the support through-pores rather than in the stagnant fluid inside the dead-end pores of the adsorbent particle as in the case of packed-bed chromatography. In membrane-based processes the transport of solute molecules to the corresponding binding sites takes place mainly by convection, while diffusion is usually involved in the mass transport within the dead-end pores of particles. This minimizes some of the common limitations of classical chromatographic beds such as process time, channeling, and intra-bed diffusion. Since a typical membrane bed (including single or stacked membranes as well as disks and monolithic columns) has a much larger cross-sectional area relative to the bed length compared with packed-bed columns, the pressure drop is drastically reduced resulting in higher flow rates and thus higher productivities. Short diffusional distances allow optimal utilization of the immobilized ligand situated at the inner surface of the membrane pores. Furthermore, ligand and product are, compared to packed columns, only for a short time exposed to harsh elution conditions, which decreases their possible denaturation. The affinity membranes also offer the possibility to operate sterile, in good conditions of reproducibility [2,13]. An additional advantage in membrane chromatography is their relative low production cost. This allows the development of disposable membrane adsorbers, which can be replaced when the desirable properties (mainly binding capacity, selectivity, or permeability) go below the efficiency value.

Membrane chromatography proved to be a successful tool especially for separation of macromolecules. The large-size proteins cannot enter the small pores of the particles in the packed-bed columns, while in membrane-based processes they have access to a much higher binding surface due to the macroporous nature of the supports. One problem may nevertheless appear for membranes with large pore distribution. Suen [182] reported that a variation of ±12% in porosity can be responsible for a loss of 50% of adsorption capacity at the breakthrough point. For variations in the membrane thickness a three times less-sensitive behavior was found.

Due to the fact that the membrane thickness is in the range of several hundreds up to thousands microns there is often a nonuniformity in the thickness as well as in the porosity within the sheets, which results in a decline of membrane performance. A variance in porosity creates channeling in the membrane, causing a tremendous loss in loading capacity. In this case, the solute molecules preferentially flow through the larger pores and quickly saturate the adsorptive-sites on such large diameter and low-surface area pores. Subsequent flow through the adsorptive saturated large pores does not result in any further capture of solute. Meanwhile, residual capacity for the adsorber located in small pores, which exhibit high resistance to flow, is not completely utilized causing a lower dynamic binding capacity. This is the main drawback of adsorber membranes compared with packed beds.

Another major advantage of membrane chromatography is their relative easy packing and scale-up, which unfortunately was not extensively investigated until now. The reader should also be aware that scaling-up to larger supports diameter could cause inefficient flow distribution across the membrane thus broadening the shape of the breakthrough curve and reducing the

separation efficiency [183]. Proper design of inlet flow distributors recently proved to diminish this problem leading to more uniform flows. However, more investigations need to be performed in the area of process and equipment design if membrane chromatography is to be a competitive separation process.

### 3.6 MASS TRANSFER IN AFFINITY COLUMNS

Mass transfer is the physical process, which involves molecular and convective transport of atoms and molecules within physical systems. The rate of mass transfer is very important because the mass transfer step has to be carried out before the reaction or the adsorption step can take place. A low mass transfer rate slows down the process thereby requiring bigger reactors or purification systems. This means that mass transfer always had to be taken into account when new processes are designed.

By the production of biologics, the manufacturers are facing two critical parameters: capacity and flow uniformity. Chromatography with gel-type particles is nowadays an established and reliable process in biotechnology. The particles are among others applied for capturing and polishing of proteins, enzymes and DNA(-fragments), or for viral and endotoxin removal. The main disadvantages of chromatographic columns, especially when using gel-type resins, are flow irregularity and channeling. This results in simultaneously adsorption and breakthrough behavior, destroying the adsorption power of the chromatographic media.

Membrane chromatography, with functionalized or particle-loaded membranes, eliminates the slow diffusional process step since the feed comprising the target molecules flows in convective mode through the activated matrix. The only conditions the membranes should possess to perform a separation with high specificity and resolution are a low flow resistance, a high density of active groups, and a low nonspecific background sorption. In theory, the adsorptive membrane efficiencies should exceed those of granular beds by a factor of ten or even higher. However, a number of anomalous mass transfer effects such as nonuniform flow, dead spaces, and extra-column dispersion have been observed.

In classical bed chromatography the majority of the active sites are located in the interior of the beads, resulting in long diffusion paths or even to exclusion of the active sites for the bigger target molecules. In contrast, the membrane chromatographic devices are three-dimensional structures with a high surface over volume aspect ratio, offering easy access for the target molecules to the active sites. The ratio of BSA (67 kDa) adsorption within Mustang Q-membranes (Pall) and Q-beads of 90  $\mu\text{m}$  is 9 where as the ratio of adsorption for DNA-plasmid (2.880 kDa) within the previous mentioned adsorbers is close to 30. This shows the exclusion of bigger molecules within the beads due to the limited pores size, whereas the membranes with big convective pores allow for a higher access for large macromolecules [184]. The binding capacity of membrane adsorbers for small proteins is lower than that of the gel-based beads, but it is still significantly higher than the adsorption capacity of nonporous rigid media.

The separation efficiency in adsorptive processes is dependent on the amount and the availability of adsorptive sites during processing. The effectiveness of an adsorber can be visualized by measuring the breakthrough curve (Figure 3.17) where the load is plotted against the eluent concentration. At a certain point, depending on the physical characteristics of the target molecule and on the capacity, the flow rate and the packing of the adsorber, the concentration in the eluent is raising. A breakthrough curve covers two different areas: the area above the curve corresponds to the operational column capacity, which after the breakthrough is the unused capacity and the area under the curve represents the product loss. The lower the breakthrough point is chosen, the smaller is the amount of product waste.

A broadly disperse breakthrough curve causes a decrease in ligand utilization, delay in saturation time, or waste of feed solution [182]. The sharpness of the breakthrough curve depends on the unique relation between the number of transfers for the

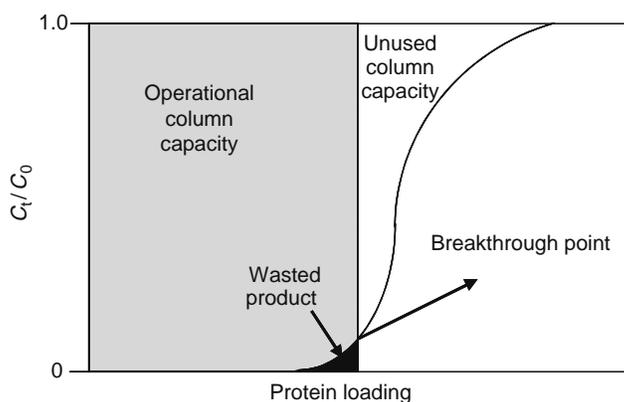

FIGURE 3.17 Visual representation of a breakthrough curve.

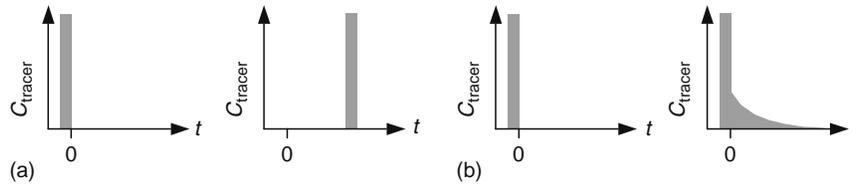

FIGURE 3.18 Tracer profiles in (a) plug flow mode and (b) ideal stirred reactor.

adsorption process ( $n$ ), the separation factor ( $r$ ), and the dimensionless effluent volume ( $V_e$ ) [185,186]. When  $r$  is smaller than 10,  $n$  is increasing quickly, while for a value of  $r$  higher than 500,  $n$  decreases rapidly with a further increase of  $r$ . According to the Thomas model [185], which assumes laminar flow through porous membranes, constant interstitial flow velocity, and neglectable concentration gradient in radial direction, the exit concentration depends only on  $r$ ,  $n$ , and  $V_e$ . The model proposed by Suen [182] is more sophisticated taking also into account the ratio of ligand capacity to feed concentration and the axial Peclet number.

### 3.6.1 DESIGN PARAMETERS

Two flow patterns are imaginable for continuous flow through a column (Figure 3.18):

- Plug flow reactor (PFR) for which defined volume elements flow through a column without mixing with other volume elements. A liquid element will travel from the inlet to the outlet for a period of time equal to the reactor volume ( $V$ ) divided by the flow rate ( $Q$ ).
- Ideal continuously stirred reactor (CSTR) for which a volume element entering the CSTR will become uniform dispersed with all the other volume elements in the reactor. The initial outlet will be equal to the ratio of the tracer volume divided by the reactor volume times the initial tracer concentration, and would then exponential decay in time.

### 3.6.2 AXIAL DISPERSED PLUG FLOW MODEL

The length-based Peclet number ( $Pe_L$ ) is determined with the axial dispersed plug flow model and it is defined as

$$Pe_L = \frac{\langle v \rangle \cdot L}{D_{ax}} = \frac{\text{Transport rate for convection}}{\text{Transport rate by diffusion}}$$

At a small  $Pe_L$  the breakthrough curve is broadened, the time of total saturation is delayed, and the breakthrough point is shifted to the front. When the  $Pe_L$  increases the breakthrough curves become steeper. For  $Pe_L$  values higher than 40 the breakthrough curve is close to the Thomas model, which assumes no axial diffusion [182,186]. Axial diffusion becomes important when using thin membranes. Since  $Pe_L$  decreases with decreasing membrane thickness, the influence of axial diffusion also decreases. When  $Pe_L > 40$  the loss of loading capacity is below 3%. The timescale for axial diffusion is much bigger than that of the radial diffusion indicating mass transfer resistance in the boundary layer. This means that the concentration gradient in radial direction can be neglected when the condition  $d_p^2/4D \leq L/v$  is fulfilled. In general, axial diffusion is neglected when the radial Peclet number ( $Pe_r$ ) is smaller than 0.04.

$$Pe_r = \frac{d_p^2 v}{4DL} < 0.04$$

When individual membranes are stacked into a column, it is advisable to use at least 30 membranes on top of each other to average out the membrane heterogeneities and the channeling effects. The pressure drop over the membrane stack should be as low as possible. Therefore, producers like Sartorius, Millipore, and Pall advise not to apply pressures  $>4$  bar.

$$\text{Fanning equation: } \Delta P = \frac{4 \cdot 24 \cdot v \cdot L}{d^2} \cdot \frac{1}{2} \cdot \rho \cdot u$$

where

$v$  = viscosity ( $m^2/s$ )

$d$  = pore diameter (m)

$\rho$  = density ( $kg/m^3$ )

$u$  = linear velocity in the pore (m/s)

$L$  = thickness of membrane stack (m)

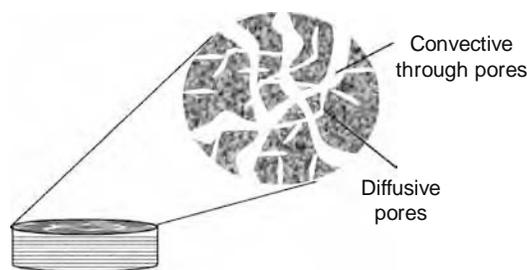

FIGURE 3.19 Visual representation of a stacked column.

For particles under viscous conditions and  $Re \leq 1$  a more simplified form, known as the Kozeny–Carman equation, can be used to calculate the pressure drop within the chromatographic column.

$$\text{Kozeny–Carman equation: } \Delta p = \frac{150 \cdot v \cdot u \cdot L \cdot (1 - \varepsilon)^2}{d_p^2 \cdot \varepsilon^3}$$

where

$d_p$  = equivalent spherical particle diameter (m)

$\varepsilon$  = void fraction of the bed (–)

$L$  = column length (m)

When diffusion inside the adsorbent is the limiting mass transfer step, two different diffusion mechanisms with different driving forces namely pore diffusion and surface diffusion have to be considered [187]. Surface diffusion is often neglectable in case of proteins for which the lumped sum is often described as effective pore diffusivity while it has to be taken into account in case of ions. However, using high surface coverage surface diffusion can really contribute to the mass flux. For high capacity membrane adsorbers the surface diffusion is the dominating factor in the mass transfer thus the shape of the breakthrough curve is strongly dependent on the feed concentration. In membrane chromatography the target solutes are transported by convective bulk flow to the active sites. The solutes experience three different resistances against transport [188].

### 3.6.3 DISPERSION

Membranes act as short wide chromatographic columns with pore sizes up to 3  $\mu\text{m}$  (Figure 3.19) resulting in very low resistance against mass transport and high fluxes of over 1000 cm/h coupled with a low-pressure drop. Longitudinal dispersion and convection of matter by flowing through a packed bed or membrane are coupled. This can be visualized by the maximum when the  $Pe_L$  number is plotted against the Reynolds number [189].

The residence time distribution (RTD), also referred to as the distribution of ages, is based on the assumption that each element traveling through the column takes a different route and will therefore have a different residence time. Different methods are developed to determine the RTD in a module or in a reactor [190]. The RTD of a chromatographic column is defined by a function  $E$  (Figure 3.20), such that  $E dt$  is the fraction of material in the exit stream with an age between  $t$  and  $t + dt$ . The  $E$ -curve lies between the extremes of plug flow and continuously stirred tank reactor. The surface below the curve between  $t = 0$  and  $t = \infty$  has to be equal to unity  $\int_0^\infty E(t) dt = 1$ , because all elements that enter the module must also exit the module.

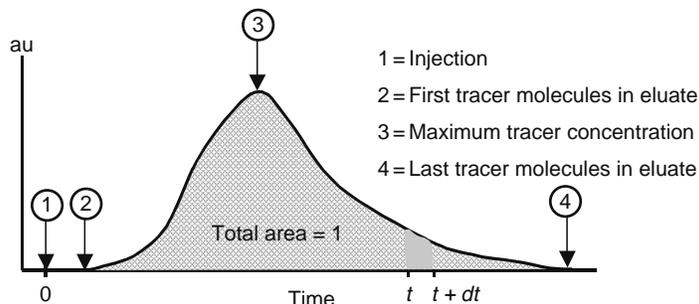

FIGURE 3.20 Example of an  $E$ -curve.

The  $E(t)$  curve is obtained out of the tracer concentrations. The existing relationship between the  $E(t)$  and  $C(t)$  is  $E(t) = \frac{C(t)}{\sum C(t)}$ . The average residence time can be determined by  $\bar{t} = \int_0^{\infty} t \cdot E(t) dt$ . This  $E(t)$  can be obtained by various methods of which the two most common are given below:

- *Tracer Impuls Method*: In this method a certain amount of tracer is injected (very short time interval) into the system and the concentration is measured at the outlet of the column. The concentration followed in time can directly be converted to the  $E(t)$  curve as described above.
- *Heaviside Step Function*: This function implies measurements of the integrated function of the distribution curve, cumulative RTD function  $F(t)$ . This can be established by changing one liquid (usually water) from one steady value to another with a detectable tracer. The equation that relates this measurement to the tracer impulse method is  $F(t) = \int_0^t E(t) dt$ .

### 3.6.4 DETERMINING THE AVERAGE RESIDENCE TIME AND THE VARIANCE

The recorded  $F(t)$  curves can be translated to the  $E(t)$  curve by taking the derivative of the recorded curve. The data were translated with  $E(t_n) = \frac{\partial F(t)}{\partial t} = \frac{F(t_{n+1}) - F(t_{n-1})}{\Delta t}$ .

First, the area under the curve is determined by the zero moment  $MO_0$ . In this way the curve can be normalized if necessary.

$$\begin{aligned} MO_0 &= \int_0^{\infty} E(t) dt = 1 = \sum_{n=0}^{n=x} \frac{1}{2} \{E(t_n) + E(t_{n+1})\} \Delta t_n \\ &= \frac{1}{2} \{E(t_0) + E(t_1)\} (t_1 - t_0) + \cdots + \frac{1}{2} \{E(t_{x-1}) + E(t_x)\} (t_x - t_{x-1}) \end{aligned}$$

Second, the average residence can be determined by calculating the first moment

$$\begin{aligned} MO_1 &= \bar{t} = \int_0^{\infty} t \cdot E(t) dt = \sum_{n=0}^{n=x} \frac{1}{2} \{t_n E(t_n) + t_{n+1} E(t_{n+1})\} \Delta t_n \\ &= \frac{1}{2} \{t_0 E(t_0) + t_1 E(t_1)\} (t_1 - t_0) + \cdots + \frac{1}{2} \{t_{x-1} E(t_{x-1}) + t_x E(t_x)\} (t_x - t_{x-1}) \end{aligned}$$

For the calculations of the variance determined by  $\sigma_t^2 = MO_2 - MO_1^2$ , it is necessary to determine the second moment

$$\begin{aligned} MO_2 &= \int_0^{\infty} t^2 \cdot E(t) dt = \sum_{n=0}^{n=x} \frac{1}{2} \{t_n^2 E(t_n) + t_{n+1}^2 E(t_{n+1})\} \Delta t_n \\ &= \frac{1}{2} \{t_0^2 E(t_0) + t_1^2 E(t_1)\} (t_1 - t_0) + \cdots + \frac{1}{2} \{t_{x-1}^2 E(t_{x-1}) + t_x^2 E(t_x)\} (t_x - t_{x-1}) \end{aligned}$$

The RTD measurement is a dynamic measurement meaning that the volume in the column measured with the experiments ( $V_{\text{flow-through}}$ ) can be determined. Static volume measurements can also be done to determine the column hold up,  $V_{\text{hold up}}$ . The average residence time,  $\tau_{V_{\text{hold up}}}$ , based on the column hold up can be determined by  $\tau_{V_{\text{hold up}}} = \frac{V_{\text{hold up}}}{Q}$ .

The following is possible:

- $\bar{t} > \tau_{V_{\text{hold up}}}$  adsorption of the tracer in the column or transport into the porous structure
- $\bar{t} = \tau_{V_{\text{hold up}}}$  completely utilized column
- $\bar{t} < \tau_{V_{\text{hold up}}}$  presence of dead volume and channeling within the column

When the determined residence time approaches the  $\tau_{V_{\text{hold up}}}$  just external flow is obtained whereas for residence time getting closer to the  $\tau_{V_{\text{accessible}}}$  value, internal flow (due to diffusion or convection) is also obtained. It may be seen that a single parameter  $\sigma_t^2 / (\bar{t})^2$  is sufficient to characterize the sharpness of the peak. The inverse of this parameter is the number of theoretical plate heights of the adsorber, which describes the efficiency of the system.

### 3.6.5 BROWNIAN MOTION

During the convective transport individual target molecules are dispersed by the presence of small eddies. The random walk motion of small particles suspended in a fluid due to bombardment by molecules obeys the Maxwellian velocity distribution. If a number of particles subject to Brownian motion are present in a given medium and there is no preferred direction for

the random oscillations, then over a period of time the particles will tend to be spread evenly throughout the medium. Thus, if two compartments one containing component A and the other containing component B are brought together then component A will move to compartment B. The speed of this transport is dependent on the concentration difference within the two compartments, the particle size, the viscosity of the medium, and the temperature. This process is called diffusion and is the macroscopic manifestation of Brownian motion on the microscopic level.

In a convective fluidum the movement of one component in a certain medium, in a time interval ( $t$ ) and in a certain direction, from its starting point over the distance ( $x$ ) is related to the diffusion coefficient ( $D$ ) of that component.

### 3.6.6 INTERACTION WITH THE MATRIX AND ACTIVE SITES

In membrane chromatography the active sites are immobilized inside the membrane pores. For particle-loaded membranes the active sites are immobilized at the outer surface of the imbedded particles or, to increase the total active surface area, they can also be located inside the porous particles. In the latest case if very small pores are involved, the productivity is low even in spite of a high active surface area. This is because the transport of the target molecules to the active sites is by diffusion alone, which is a much slower process than the convection through the big pores. Therefore, the loading step is much more time-consuming. The interaction between the target molecules and the ligands is often considered instantaneous. Nevertheless, in the case of affinity complex formation the building of the complex can be that slow that the limiting step is not longer the convection or the diffusional transport to the active site but the complex formation.

## 3.7 ADSORPTIVE MEMBRANE GEOMETRY AND OPERATION MODES

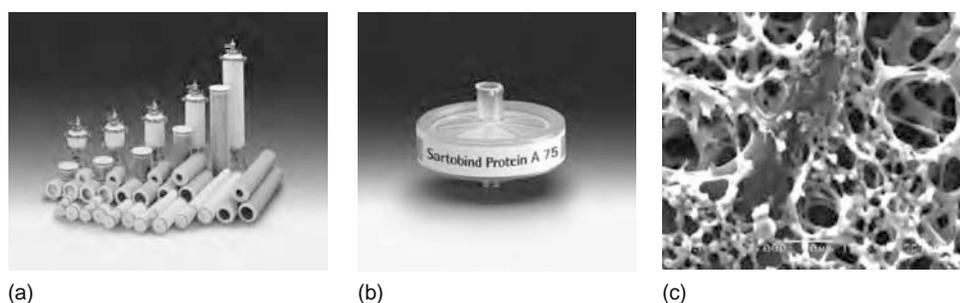

Membrane chromatography can be performed on units of various geometry, microporous adsorptive membranes and related systems such as single or staple flat-sheet membranes, hollow-fiber, spiral-wound and cassette devices being already commercially available. An overview of commercially available supports in membrane chromatography is presented in Table 3.3. Few of these systems (Sartobind, Sartorius [Figure 3.21]; MemSep, Millipore; Quik Bind, Sepracor; Biorex, Bio-Rad; Lowprodyne, Pall; AbSorbent, Genex; ActiDisk, FMC Bioproducts; MAC, Amicon) have been already developed for a small number of technical applications [8–10].

Continuous beds including methacrylate-based disks CIM QA from BIA Separations (Figure 3.22) and SWIFT from Isco, acrylamide UNO monoliths from Bio-Rad, Ultimate polystyrene divinylbenzene disks from LC-Packings, cellulose-based Seprisorb monoliths from Sepragen and silica units Conchrom from Conchrom or Chromolith from Merck are also

**TABLE 3.3**  
**Examples of Commercially Available Membrane and Monolithic Products**

Trade Name	Manufactures	Module Type	Material	Separation Principle
Sartobind, Vivapure	Sartorius, Vivascience (Germany)	Flat sheets, disks	Regenerated cross-linked cellulose	IEX, AF, IMAC
Immobilon, Intercept Q, MemSep, Zip Tip	Millipore (USA)	Flat sheets, syringe, disks, pipette tips	PVDF, regenerated cellulose, silica, polypropylene	AF, IEX, RP
ActiDisk	FMC (USA)	Flat sheets	PVC	IEX
ZetaPlus/PolyNet	Cuno Life (USA)	Depth filter	Cellulose, polypropylene	IEX
Biodyne, Mustang (Q, S, and E)	Pall (USA)	Flat sheets, disks	Nylon, PES	IEX, AF
Fractoflow, Chromolith	Merck (Germany)	Hollow fibers, monolithic rods	Polyamide, silica	IEX, RP
Empore	3M	Particle-loaded membranes, disks	PTFE, PS-DVB, silica	IEX, AF
Mosaic Systems	Mosaic Systems (The Netherlands)	Particle-loaded membranes, full/hollow fiber modules	PES	IEX, AF
Seprisorb	Sepragen (California, USA)	Monolithic columns	Regenerated cellulose	IEX
CIM disk	BIA (Slovenia)	Monolithic rods, disks, tubes	Polyglycidyl methacrylate-co-ethylene dimethacrylate	IEX, RP, AF
Swift	Isco (USA)	Monolithic columns	Styrene, methacrylate	IEX, RP
Conchrom	Conchrom (Germany)	Monolithic rodss	Modified silica	IEX, RP
UNO	Biorad (California, USA)	Monolithic rods	Polyacrilamide	IEX

Note: IEX = ion-exchange chromatography; AF = affinity chromatography; IMAC = (metal-)chelate chromatography; RP = reversed-phase chromatography.

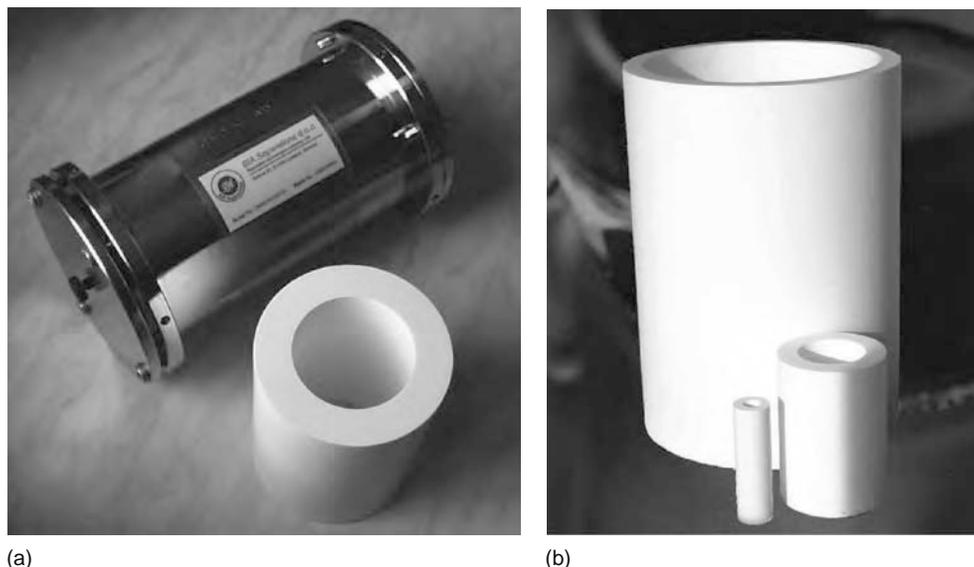

**FIGURE 3.21** (a) Layered membrane adsorbers, (b) lab-scale membrane adsorber, and (c) higher magnification membrane adsorber. (Courtesy Sartorius, Göttingen, Germany.)

manufactured as large scale. The smaller laboratory scale systems often contain various amounts of stacked flat sheet membranes; single sheet adsorbers are rarely used. The bigger process systems consist of radial fed layered or layered and pleated sheets [184]. For an optimal design of the membrane chromatographic systems several parameters have to be taken into account.

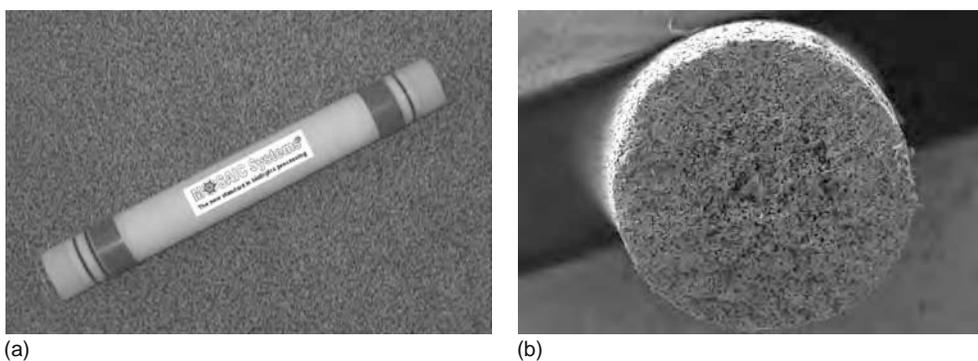

Most commercial systems like Mustang from Pall and Sartobind from Sartorius make use of functionalized microporous membranes. The fibrils reinforced membranes are (pleated) layered around a porous core. The feed is forced to permeate through the membranes in radial direction. This approach results in high area to volume ratio. The 3M and Mosaic Systems approach is different. Instead of functionalization of a porous support they make use of already functionalized beads, which are embedded in a porous support. In this approach, the beads are responsible for the capacity and selectivity where the porous matrix controls the hydrodynamics. The 3M modules consist of stacked flat sheet or pleated membranes, while Mosaic Systems makes use of porous fibers in which the active particles are embedded (Figure 3.23).

In processes where large macromolecules with slow associated kinetics are involved, the adsorption kinetics between the ligand and the dissolved molecule in the feed solution is the rate-limiting step. Not often the pressure drop or the membrane mechanical strength is the limiting factor. When thin membranes are applied the axial diffusion also becomes more dominant and requires a lower linear flow rate through the matrix. Besides this in-homogeneities in porosity and thickness affect the performance of the system negatively. To overcome this problem, often a stack of at least 30 membrane sheets are stacked to average out these heterogeneities.

By using hollow fiber membranes the ideal module comprises short fibers with a wide bore to avoid a high pressure drop in the flow direction thereby disturbing the uniform radial flow pattern and creating channeling. The membranes should also possess thick porous walls with small pore size and a high ligand density. The hollow fiber modules can be operated in cross flow mode what makes them especially suitable in the treatment of solutions containing particulate material.

### 3.8 APPLICATIONS OF MEMBRANE CHROMATOGRAPHY

The operating interactions within the microporous media involved in chromatographic separation processes are identical to those in the packed columns including affinity interactions, size-exclusion, ion exchange, hydrophobic interactions, and reverse phase (Table 3.4). The functional groups immobilized on the porous membrane surface include, depending on the target application, (i) affinity ligands, e.g., Protein A/G, BSA, biomimetic dyes, immobilized metal, various hydrophobic amino acids; (ii) ion-exchange groups such as carboxylic or sulfonic acid, tertiary or quaternary amines; and (iii) hydrophobic ligands, e.g., octyl and phenyl groups. Several detailed reviews of the various applications of membranes in chromatographic separations have been recently published [8–13]. Therefore, in the following, we will give just a short overview of some of the successful applications of membrane chromatography, classified as a function of the interaction mode involved in the separation process. Readers should also take into account the possible application of membrane chromatography already mentioned in Section 3.3. The different modes of chromatography reports are briefly summarized in Table 3.5. Detailed overview of tables on application in membrane chromatography may be found in Refs. [8,12,13].

The affinity techniques performed on single or stacked membranes, disks, tubes, and rods are based on a biospecific interaction that results in a change of protein properties such that the protein can be separated from other complex biomolecule-containing mixtures. The ligand molecule is immobilized on the porous surface and the mixture containing the protein of interest is passed through the adsorptive membrane. A specific interaction takes place between ligand and ligate and retains the desired protein within the matrix support, while the other components from the feed solution pass freely through the adsorber. Affinity chromatography allows for purification of biopolymers based on biological functions rather than individual physical or chemical properties. Isolation of a protein or a group of proteins such as  $\gamma$ -globulin fractions, human serum albumin, and various clotting factors from body fluids was successfully achieved by using affinity membrane chromatography.

Immunoaffinity techniques were widely employed for the analyses and purification of proteins [191–193]. Immobilized antibodies were used, e.g., for industrial scale production of human interferon- $\alpha$ 2a, interleukin-2, and interleukin-2 receptor, while protein A and protein G were successfully used in therapeutic applications including purification of human immunoglobulin G from plasma and serum [194–196].

Pseudoaffinity ligands such as dyes, lysine, and histidine are now well established in membrane chromatography. Cibacron Blue F3GA dye membranes (having a specific binding for nicotinamide adenine dinucleotide dependent enzymes) and Procion Red HE-3B (with a specific binding for nicotinamide adenine dinucleotide phosphate dependent enzyme) were successfully employed in purification of several enzymes including human serum albumins from plasma, dehydrogenases

**TABLE 3.4**  
**Types of Interactions Involved in Chromatographic Separation Processes**

Type of Chromatography	Separation Mode/Interaction Type
Affinity chromatography	Molecular structure/biospecific adsorption
Ion-exchange chromatography	Surface charge/ionic binding
(Metal-)chelate chromatography	Metals complex formation/coordination complex
Size-exclusion chromatography	Molecular size and shape/size exclusion
Normal/reversed-phase chromatography	Hydrophobicity/hydrophobic complex formation

**TABLE 3.5**  
**Examples of Membrane Chromatographic Applications**

Separation Mode	Ligate Type	Ligand Type	References
Affinity chromatography (immunoaffinity, metal affinity, chiral)	Human interferon- $\alpha$ 2a, interleukin-2 receptor, human IgG, human serum albumin, dehydrogenases glucose-6-phosphate dehydrogenase, formate dehydrogenase, pyruvate decarboxylase, S-oxynitrilase, bovine liver catalase, recombinant protein G, plasmid DNA, human blood coagulation factor VIII, enantiomers of kynurenine, tryptophan, $\beta$ -blockers, practolol, thiopental	Antibodies, protein A and protein G, lysine, histidine, Cibacron Blue F3GA, Procion Red HE-3B, combinatorial peptides, metals	[36,135,191–201, 218–225]
Ion exchange	Serum proteins, microbial proteins and enzymes, membrane proteins, cytokines or nucleic acids, BSA, HSA, $\alpha$ -chymotrypsinogen, lysozyme, trypsin inhibitor, cytochrom c, ovalbumin, $\alpha$ -lactoalbumin, conalbumin, ferritin, myoglobin, chymotrypsin, human recombinant antithrombin, monoclonal and polyclonal antibodies, immunofusion proteins	Quaternary amino, diethylaminoethyl groups	[36,58,202–211, 222–224,226]
Hydrophobic interaction/reverse phase	Recombinant tumor necrosis factor, myoglobin, ovalbumin, lysozyme and chymotrypsinogen, chymotrypsinogen A, ribonuclease, myoglobin, trypsinogen and lysozyme, tricyclic antidepressants, antiarrhythmic drugs, amiodarone, desethylamiodarone, mexiletine, flecainide, alcohols, phenols, aldehydes, ketones, esters, polar pesticides from water	C <sub>4</sub> , C <sub>6</sub> , C <sub>8</sub> , or C <sub>10</sub> linear aliphatic chains	[2,14,205,212–217,226]

glucose-6-phosphate dehydrogenase from a clarified yeast solution, formate dehydrogenase from *Candida bodinii* and pyruvate decarboxylase from *Zymomonas mobilis* homogenates [36,197].

Applications of metal affinity chromatography include separation of S-oxynitrilase from *Sorghum bicolor* on IDA-Cu<sup>2+</sup> ion membranes, purification of human serum albumin with an IDA-Ni<sup>2+</sup> membranes cartridge and purification of bovine liver catalase (both on an analytical and preparative scale) by IDA-Cu<sup>2+</sup> composite cellulose membrane [198,199]. A unique application for affinity purification is the separation of proteins differing by a single histidine molecule in their sequence by immobilized metal affinity chromatography.

Kasper et al. [200] proposed an affinity-chromatographic method for a fast, semipreparative isolation of recombinant protein G from *Escherichia coli*. Rigid, macroporous affinity discs based on a GMA-co-EDMA polymer were used as chromatographic supports. Human immunoglobulin G was immobilized by a single-step reaction. The globular affinity ligands were located directly on the pore wall surface and were therefore freely accessible to target molecules (protein G) passing with the mobile phase through the pores.

Examples of bioaffinity separations using monolithic stationary phases based on antigen-antibody, enzyme-substrate, enzyme-inhibitor, receptor-ligand interactions were reviewed recently [201]. Giovannini et al. [202] prepared poly (GMA-co-EDMA) membranes for the separation of supercoiled plasmid DNA. Gradient and isocratic elution was investigated and high-performance membrane chromatography experiments were compared with similar ones performed on a conventional packed-bed column. Amatschek et al. [135] developed an affinity-chromatographic method in which peptides, derived from a combinatorial library, were used as immobilized ligands for the purification of human blood coagulation factor VIII. Affinity monoliths based on a copolymer of glycidyl methacrylate and ethylene dimethacrylate using rabbit IgG and anti-FITC antibodies as ligands were recently developed for ultrafast immunoextractions [203].

Ion-exchange chromatography is probably the most widely used chromatographic method for protein separation. The principle of protein separation by ion exchange is the electrostatic interaction between the charges of the macromolecule and the adsorber surface. The protein must displace the counter ion of the exchangers and become attached on the sorbent's surface. The amount of macromolecule bound per unit volume of adsorptive membrane can be very high. However, for most exchangers, the binding capacity depends on the molecule size of the protein and adsorption conditions (pH, ionic strength, and protein concentration). Ion-exchange membranes can be produced by modification of commercially available microfiltration membranes.

Anion-exchange chromatography on membranes, disks, and rods bearing mainly quaternary amino groups or diethylaminoethyl groups as ligands has been used for the separation of serum proteins, microbial proteins and enzymes, membrane

proteins, cytokines, or nucleic acids [36,58,204–209]. BSA and HSA,  $\alpha$ -chymotrypsinogen, lysozyme, trypsin inhibitor, cytochrome c, ovalbumin,  $\alpha$ -lactoalbumin, conalbumin, ferritin, myoglobin, and chymotrypsin are just a few of the compounds isolated by anion-exchange membrane chromatography. The implementation of a CIM DEAE (diethylaminoethyl) monolith-based step into a large-scale plasmid DNA purification process was recently performed [210].

Cation-exchange membranes, despite the fact that they are not as widely investigated as that of anion-exchange membranes, allow recovery of human recombinant antithrombin from cell culture supernatants, purification of monoclonal and polyclonal antibodies, and isolation of immunofusion proteins produced extracellularly by *E. coli* [211–213]. The separation of similar size proteins such as serum albumin and hemoglobin using adsorber membranes loaded both with cation or anion-exchange particles was recently reported [214]. Li et al. [215] have used a cation-exchange monolith (prepared by polymerization of aqueous solution of appropriate monomers including the desired ligand directly in a fused-silica tube), as chromatographic supports for separation of four standard proteins (cytochrome c, lysozyme, myoglobin from horse and whale). High adsorption of lysozyme on macroporous chitosan carboxymethyl/cellulose blend membranes was recently reported [216].

The protein separations based on hydrophobic interactions and reverse phase use the interaction between aliphatic chains on the adsorbent and corresponding hydrophobic regions on the protein surface. Typical hydrophobic adsorbents commercially available include C<sub>4</sub>, C<sub>6</sub>, C<sub>8</sub>, or C<sub>10</sub> linear aliphatic chains, eventually with a terminal amino group. The main problems in hydrophobic chromatography are the slow association–dissociation processes and protein–protein interactions. Similar proteins can interact with each other as well as with the adsorbent leading to a large degree of overlapping between the elution components.

Hydrophobic chromatography has not been used in protein separation as intensive as ion exchange or affinity chromatography since sharp separations are not achieved. Nevertheless, chromatographic units with butyl ligand were used for purification of the recombinant tumor necrosis factor [207]. Tennikova et al. [2] reported separation of a protein mixture containing myoglobin, ovalbumin, lysozyme, and chymotrypsinogen on monolithic columns with C<sub>4</sub> or C<sub>8</sub> ligands. Zeng et al. [217] reported intensive studies on the preparation of monolithic stationary phases based on acrylic comonomers including piperazine diacrylamide, methacrylamide, and *N*-isopropylacrylamide for application in hydrophobic interaction chromatography of proteins. Chymotrypsinogen A, ribonuclease, myoglobin, trypsinogen, and lysozyme could be recovered with estimated values ranging from 91% to 99%. PS-*co*-DVB continuous rods were also investigated for the reversed-phase separation of proteins, alkylbenzenes, and peptides [218,219].

Particle-loaded membranes with embedded C<sub>8</sub> hydrophobic adsorbents were intensively investigated for several drug separations. Tricyclic antidepressants, antiarrhythmic drugs, amiodarone and its metabolite desethylamiodarone, and mexiletine and flecainide were extracted from serum using a 11 mm C<sub>8</sub> membrane adsorber with recoveries ranging from 82% to 98% [14,220].

Highly hydrophobic sorbents including porous carbon and copolymers of styrene and divinylbenzene (SDB) were widely investigated for environmental applications. The particle-loaded membranes containing modified SDB particles with surface sulfonic acid groups were successfully used for recovering different alcohols, phenols, aldehydes, ketones, or esters from aqueous samples [221]. Carbon-based PLM were also used for isolation of highly polar pesticides from water [222].

Chiral crown ether bonded on negatively charged polyacrylamide gels was prepared by Koide et al. [223] for enantiomeric separation of primary amino compounds with high efficiency and good reproducibility. Monolithic columns prepared by free radical polymerization of piperazine diacrylamide and methacrylamide in the presence of acetylsalicylic acid and L-tryptophan as additives were recently reported [224]. The monoliths, carrying immobilized human serum albumin as chiral selector, showed improved resolution when used for kynurenine and tryptophan enantiomeric separation. Continuous polymeric beds prepared either by entrapment in and simultaneous covalent linkage of allyl cellulose to the polymeric bed during preparation or by covalent immobilization of cellulose on an epoxy-activated continuous bed were investigated for enantiomers separation by Mohammad et al. [225]. Enantiomers of  $\beta$ -blockers and practolol were rapidly separated with good resolution.

Wang et al. [226] prepared a microfluidic system containing porous PVDF and PDMS membranes impregnated with bovine serum albumin as chiral chromatographic support. On-line BSA adsorption onto the membranes was employed for the preparation of chiral stationary phase allowing separation of racemic tryptophan and thiopental mixtures with high resolution. Chiral separation of racemic tryptophan, phenylglycine, and phenylalanine was also investigated through immobilized DNA membranes [227].

Multistage chromatography combines different types of chromatographic supports to achieve a higher degree of selectivity. A sequence of three membrane-based separation steps (including cation exchanger, dye-ligand, and anion-exchange membranes) enabled the purification of formate dehydrogenase from *C. bovidinii* [228] in micro- and laboratory scale. Using a sequence of ultrafiltration, diafiltration, Cibacron blue, anion exchanger, and heparin-membrane adsorber, pure recombinant human antithrombin III was obtained from hamster cell culture.

Branovic et al. [229] combined affinity and ion-exchange chromatography in a single column used to determine the impurities in immunoglobulin preparation. In their method, a monolithic disk bearing immobilized protein G with the leading role of retaining the immunoglobulins was placed on top of an ion-exchange disk, which could capture the impurities. Using specific elution conditions the immunoglobulins could be separated. A strong ion-exchange membrane adsorber carrying

**TABLE 3.6**

	Packed Bed		Membrane Adsorber		
	Big Beads	Small Beads	Particle Loaded	Chemical Functionalized	Monolithic Column
Capacity	+	++	+	+-	+-
Flow rate	+	-	++	++	++
Productivity	+	+	++	+	+
Resolution	+-	++	+	+	+
$\Delta P$	++	--	++	++	+
Prepurification	+	--	+	+	+-

sulfonic acid or quaternary ammonium groups and a Cibacron blue immobilized affinity adsorber were also investigated for mixed-mode interactions chromatography of standard protein mixtures as well as for the separation of whey proteins (BSA, IgG,  $\alpha$ -lactalbumin, and  $\beta$ -lactoglobulin) and recombinant human antithrombin III from biotechnological culture supernatants [230]. Using a series of four continuous beds each carrying a different affinity ligand, the one-step fractionation of four different antibodies from biological mixtures was achieved [231].

A mixed particle-loaded membrane consisting of a C<sub>8</sub> or C<sub>18</sub> hydrophobic adsorbents and a strong cation-exchange material can be used for selective extraction of pigments or imiquimod metabolites from urine with up to 95% recovery [232].

### 3.9 CONCLUSIONS

Packed-bed chromatography is still the standard method involved in capturing and polishing of biomolecules despite some major disadvantageous such as sensitivity to fouling and plugging, bed consolidation and compression, and high pressure drop and long cycle times. Membrane chromatography has obvious advantages over packed bed (Table 3.6). It uses microporous membranes that contain biospecific ligand molecules attached to their inner pore surface, as adsorbents. As a result of the convective flow of the feed solution through the porous structures the mass transfer resistance is tremendously reduced and the binding kinetic is usually dominating the adsorption process. This results in rapid processing and improved adsorption, washing, elution and regeneration steps, and minimize the probability of protein denaturation.

The technology is robust, fast and able to process huge volumes containing low concentrations of target molecules. Especially in the area where packed beds have severe shortcomings because of their limited pores size, for example, DNA recovery and virus removal, the membrane chromatography has a good opportunity to expand till market leader. The advantages of membrane chromatography have been confirmed by many successful applications. Nevertheless there is a scope for further improvement of the adsorptive membrane design by increasing the binding capacity, extension of the supplied ligands, and optimization of the hydrodynamics, and to assess the use of membrane chromatography in large-scale processes. In the near future, membrane chromatography may be the synergetic outcome of two mature techniques, chromatography and filtration that are at this moment the standards in biologic processing.

# 4 Membranes in Gas Separation

*May-Britt Hägg*

## CONTENTS

4.1	Introduction .....	66
4.2	Transport Mechanisms for Gas through Membranes .....	68
4.2.1	Solution Diffusion .....	69
4.2.2	Knudsen Diffusion .....	71
4.2.3	Selective Surface Flow .....	71
4.2.4	Molecular Sieving .....	72
4.2.5	Ion-Conductive Transport .....	73
4.2.5.1	Proton-Conducting Membranes .....	73
4.2.5.2	Oxygen-Conducting Membranes .....	73
4.2.6	Facilitated Transport .....	74
4.3	Membrane Materials Used for Gas Separation .....	74
4.3.1	Polymeric Membranes .....	74
4.3.1.1	Polymers Receiving Special Interest .....	78
4.3.1.2	Fixed-Site Carrier Polymers .....	79
4.3.2	Carbon Molecular Sieving Membranes .....	80
4.3.2.1	Separation Properties for CMS Membranes .....	81

## 4.1 INTRODUCTION

The application of membranes for gas separation is a fairly young technology compared to the use of membranes for liquid separation. Although the basic theoretical principles were partly understood and date back to the early nineteenth and twentieth century with Fick's law (1855), osmotic pressure (Van t'Hoff, 1887 and Einstein 1905), and membrane equilibrium (Donnan 1911), it was not until around 1950 that theories for gas transport through a membrane were presented and later further developed (pore model by Schmid in 1950 and Meares in 1956, solution-diffusion model by Lonsdale in 1965) [1]. The breakthrough for industrial membrane applications came with the development of the asymmetric membranes achieved by Loeb and Sourirajan around 1960 [2]. These membranes were developed for reverse osmosis and consisted of a very thin dense top layer (thickness <0.5 μm) supported by a thicker porous sublayer; hence the flux which is inversely proportional to the selective membrane thickness could be dramatically increased. The work of Loeb and Sourirajan resulted in commercialization of the reverse osmosis process for desalting of water, and had also a major impact on the further development of ultrafiltration and microfiltration processes. The development of gas separation membranes is based on their achievement and about 20 years later (~1980) the work of Henis and Tripodi made industrial gas separation economically feasible. They developed further the technique of putting a very thin homogenous layer of a highly gas permeable polymer on top of an asymmetric membrane, ensuring that pores were filled so that a leak-free composite membrane for gas separation was obtained. The first major development was the Monsanto Prism membrane for hydrogen recovery from a gas stream at a petrochemical plant [3]. Within a few years Dow Chemical Company was producing systems to separate nitrogen from air, and Cynara NATCO Group and Separex UOP LLC systems for separation of carbon dioxide from natural gas. These first membranes were all composite membranes where a very thin nonporous layer with high gas permeation rate (usually polysulfone or cellulose acetate (CA)) was placed on a support structure for mechanical strength—later other techniques for membrane formation were developed (i.e., interfacial polymerization, multilayer casting, and coating).

The interest from industry in membrane gas separation has nearly exploded over the last 10–15 years—the potential is enormous. So what are the attractive features to industry of membrane gas separation? The most obvious answer is the simplicity of the separation process. The standard units for gas separation usually involve large towers for absorption towers or stripping, adsorption beds, cryogenic distillation, large compressors, recovery and recycling of chemicals, all resulting in expensive and energy-demanding processes—not always without harmful effects to environment. This does not mean that a membrane process will be more economical nor as efficient as the traditional separation process used. However, as the trend goes, the development of tailor-made membranes for specific gas applications will most likely continue to bring the technology into focus as an attractive, economical, and environmental friendly alternative for gas separation. In theory the limitations are few for membrane applications, but in practice the challenges to succeed are numerous. For each application process, conditions must be taken into account (volume and composition of gas stream, pressures and temperatures, durability of the material), as the membrane separation properties may vary dramatically depending on these variables. This means that focus also must be on utilities and pretreatment of the gas in order to evaluate the economics and performance of the membrane process. Quite often a hybrid process combining membranes and standard unit operations may be the best solution.

As a general rule, the driving force of membrane gas separation is the difference in partial pressures (concentrations) between feed side and permeate side. It is however more correct to say that the driving force is the difference in chemical potential, thereby including the effect of temperature. An additional driving force may be an electric potential or a carrier effect for certain types of membranes. New membrane materials may combine different transport mechanisms, and thereby increase the flux and selectivities. A more detailed discussion on these issues will be given in Section 4.2.

The need for optimized membrane separation properties for specific gas mixtures kicked off an explosive development with respect to tailor-made polymeric membrane materials in the mid-nineties. The approach had until then been to look at existing polymeric materials and try to tailor separation properties by making moderate changes in the material. This could be done by synthesizing families of polymers (for instance polyimides, polycarbonates) with different fractional free volume (FFV) and glass transition temperature ( $T_g$ ), by using various methods for crosslinking or combining polymers like block copolymers.

**FIGURE 4.1** Selectivity for the gas pair  $O_2-N_2$  as a function of  $O_2$  permeability. Properties of materials like molecular sieves and mixed matrix are expected to be found in the upper right corner (hatched area; modified Robeson plot). (From Singh A., Koros W.J., *Ind. Eng. Chem. Res.*, 35, 1231, 1996. With permission.)

Then in 1991 the now so well-known Robeson plot for polymeric membranes was published [4], an upper performance limit which has later challenged membrane scientists all over the world. New types of membrane materials started to emerge, challenging the separation properties shown in this plot. A new class of materials for gas separation was brought into focus: the carbon membranes. The concept of carbon membranes was known already around 1970, but it was not until the late 1980s with the published results of Koresh and Soffer that [5] these membranes caught general interest. Several scientists have later reported impressive gas separation properties with carbon molecular sieve (CMS) membranes pyrolyzed from different precursors [6–8]. In 1996, Singh and Koros presented a revised Robeson plot which included the potential of the CMS membranes (see Figure 4.1) [9]. Around the same time a patent for making such membranes on a commercial scale was obtained by Soffer et al. [10]. Later development has shown that despite excellent separation properties, also at high temperatures, these membranes are fairly brittle and expensive to process, so there is a need to find cheap precursors and secure mechanical strength in order to make them an economically good choice. The development following the pyrolyzed carbon membranes was actually one step back, now trying to combine the excellent separation properties of the carbon membranes with the more robust polymers—the mixed matrix membranes (MMM) are today in focus as a group of membranes with very high expectations. And parallel to this development, polymeric functionalized membranes, nanocomposite materials, as well as new block copolymers are being reported with intriguing gas separation properties—this is elaborated on in Section 4.3.

Inorganic materials usually possess superior chemical and thermal stability compared to polymers. However, their use as gas membrane materials has been limited up to now. The only application in the past was the enrichment of uranium hexafluoride ( $^{235}U$ ) by Knudsen flow through a porous ceramic membrane. Today a growing interest is being observed, and new materials are being developed for gas separation. Zeolite membranes have very narrow pore-size distribution, and are usually prepared by sintering or solgel processes. In combination with organic surface treatment for pore tailoring, acceptable gas separation properties have been reported. A good overview on inorganic membranes for gas separation is given by Burggraaf [11].

Last but not least, special membranes being 100% selective for a specific gas component should be mentioned. One of the most interesting materials is the metal palladium-based membranes for transport of hydrogen as proton through the membrane. This is especially interesting for fuel cells where high purity hydrogen is needed. Ceramic oxygen-conducting membranes producing high-purity oxygen have been reported by several investigators [12,13]. All these inorganic membranes are suitable

for high-temperature applications. The separation properties for these materials are excellent, and a significant breakthrough may be in the near future. The challenge will however still be the module making (brittle!) and price of the materials.

Membranes with carrier-facilitated transport for specific gas components have also been in focus for some years, but some of these membranes studied seem to be “dead-end” developments. Of special interest are however those reported for CO<sub>2</sub> capture, either as liquid membranes or as fixed-site carriers (FSC) in polymers [14,15].

All the materials mentioned above are discussed in the current chapter. If possible, SI units are applied for the data—the reader may find a useful table for conversion of units in Ref. [16]. Many good review papers and chapters in books on membranes for gas applications have been published recent years; only a few are referred to here [17–19]. A rich source of information on membrane materials and gas separation may also be found on the Web site of membrane producers and research institutes. One example is MTR [20].

## 4.2 TRANSPORT MECHANISMS FOR GAS THROUGH MEMBRANES

The most common types of membranes for gas separation in use today are still the dense polymeric materials where transport takes place according to a solution-diffusion mechanism with flux based on Fick’s law (Equation 4.1). For the microporous membranes (inorganic or hybrid), the transport mechanisms may be according to one of the following mechanisms or combinations of these: Knudsen diffusion, selective surface flow, or molecular sieving. The average pore size and pore-size distribution is important since it will give an indication of which transport mechanism can be expected to be dominant for a given gas mixture in a defined material and at given process conditions.

Fick’s law gives the mass flux through an area perpendicular to the flow direction:

$$J_i = -D_{ij} \frac{dc_i}{dx} \quad (4.1)$$

where

$J_i$  is the flux of component  $i$  (mol/(m<sup>2</sup> s))

$D_{ij}$  is the diffusion coefficient (m<sup>2</sup>/s)

$dc_i/dx$  is the concentration gradient for component  $i$  over the length  $x$  (mol/(m<sup>3</sup> m))

Fick’s law integrated and applied for a membrane yields  $dx = l$  (membrane thickness), and  $dc_i = \Delta p_i$  (concentration difference (i.e., partial pressures for gases) over the membrane.  $D_{ij}$  will vary according to the dominating transport mechanism.

The permeance  $P/l$  [mol/(m<sup>2</sup> Pa s)] (SI units) for a given gas ( $i$ ) is defined by

$$\frac{P_i}{l} = \frac{J_i}{\Delta p_i} \quad (4.2)$$

$P/l$  is also referred to as permeability flux and expressed as (m<sup>3</sup> (STP)/(m<sup>2</sup> bar h)).  $\Delta p_i$  is the partial pressure difference of “ $i$ ” across the membrane measured in pascals or bars. This equation shows that the flux through the membrane is proportional to the pressure difference across the membrane and inversely proportional to the membrane thickness. For selectivity between gas components the Equations 4.3 and 4.4 are referred to. The “ideal” separation factor,  $\alpha^*$  (Equation 4.3), may be expressed by the ratio of the pure gas permeabilities for the individual components  $i$  and  $j$ .

$$\alpha_{ij}^* = \frac{P_i}{P_j} \quad (4.3)$$

The separation factor for gases in mixture  $\alpha_{ij}$  (Equation 4.4) is expressed by the mole fractions of the components in the feed ( $x$ ) and the permeate ( $y$ ), respectively:

$$\alpha_{ij} = \frac{y_i/y_j}{x_i/x_j} \quad (4.4)$$

The permeability,  $P$ , can be expressed as the product of diffusion ( $D$ ) and solubility ( $S$ ) of the gas through the membrane (Equation 4.5):

$$P = D \cdot S \quad (4.5)$$

Depending on type of gas and type of membrane material, the importance of these two variables,  $D$  and  $S$ , will vary. Both the diffusion and the solubility coefficient for the gas are temperature dependent, while a pressure dependency is only observed for certain gases and materials.

Dense inorganic or metallic membranes for gas separation are usually ion-conducting materials, while membranes with carriers are polymers or supported liquid membranes (SLM). For transport through these materials, different flux equations should be applied. Figure 4.2 sums up and generalizes the various types of transport, which may take place in gas-separation membranes [21].

### 4.2.1 SOLUTION DIFFUSION

The transport of gas (permeability) through a dense, polymeric membrane can be described in terms of a solution-diffusion mechanism with permeability expressed as in Equation 4.5.

Type	Typical features of current primary membrane types
A. Asymmetric polymeric solution diffusion	<p>Thin selective skin layer (0.1 μm) Highly porous support (250 μm OD) (0.1–10 μm) <math>D_i = f_i \lambda_i^2 / 6</math> Diffusion step</p>
B. Molecular sieving (zeolite or carbon)	<p>Reverse selective skin layer (0.1 μm) Highly porous support layer (Wide range of sizes and morphologies)</p>
C. "Reverse selective" surface diffusion	<p>Reverse selective skin layer (1–5 μm) Highly porous ceramic or carbon support (7600 μm)</p>
D. Complexing and reactive	<p>e.g., O<sub>2</sub> carrier facilitated membranes N<sub>2</sub>, O<sub>2</sub>, Air e.g., palladium alloy membranes for H<sub>2</sub> H<sub>2</sub> → H<sub>2</sub> → 2H</p>
E. Proton exchange (PEM) (e.g., Nafion)	<p>750 μm PEM H<sup>+</sup> Load Hydrogen source Fuel cell</p>
F. Solid oxides	<p>1000 μm O<sup>2+</sup> Load Air Fuel cell</p> <p>1000 μm O<sup>2-</sup> 2e<sup>-</sup> Air Oxidative coupling membrane reactor</p>

Note: 1 Barrer =  $7.52 \times 10^{-15} \text{ m}^3 \text{ (STP)/mm}^2 \text{ s kPa}$ .

The thermodynamic parameter,  $S$ , gives the pressure normalized amount of gas sorbed in the membrane under equilibrium conditions. This parameter is usually very low for gases in polymers, but will vary depending on physical properties of the gas (ideal, nonideal) and state of the polymer (glassy or rubbery). The state of the polymer is characterized by the material's glass transition temperature,  $T_g$ . Above  $T_g$  the polymer is in its rubbery state, and below  $T_g$  it is glassy. In glassy polymers the segmental motions of the chains are more restricted, and these materials are therefore able to discriminate more effectively between small differences in molecular dimensions. They exhibit an enhanced mobility selectivity compared to rubbery polymers. Table 4.1 shows a comparison of permeabilities and selectivities for both a rubbery (PDMS) and a glassy (PC) polymer. Crystallinity in a polymer will also restrict the gas transport.

For ideal systems (usually as in elastomers), the solubility will be independent of concentration and the sorption curve will follow Henry's law (Equation 4.6), i.e., gas concentration within the polymer is proportional to the applied pressure. For nonideal systems (usually as in glassy polymers), the sorption isotherm is generally curved and highly nonlinear. Such behavior can be described by free-volume models and Flory–Huggins thermodynamics—comprehensive discussions on this may be found elsewhere [1,25,26].

$$c_i = S_i p \quad (4.6)$$

The diffusivity,  $D$  (see Equation 4.5), is a kinetic parameter, and is dependent on the geometry of the polymer as well as its state (glassy, rubbery, swollen, etc.). A small molecule will more easily diffuse through a polymer than a larger one; however, large (organic or nonideal) molecules may have the ability to swell the polymer, hence large diffusion coefficients result and “reverse selectivity” may be observed. It is quite clear that the interdependency of molecular size, ideal or nonideal gases in mixtures, and structure and state of the polymer must be carefully evaluated in order to fully understand transport through polymers. This fundamental understanding will also govern how a membrane material may be best tailored for a given separation. For illustration of the complexity, Figure 4.3 shows the diffusion and sorption coefficient for some gases through natural rubber [27].

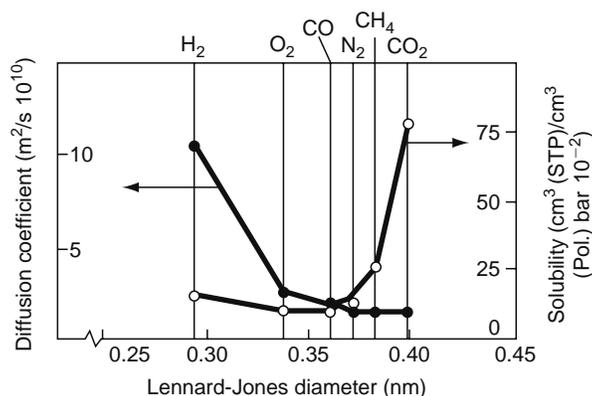

FIGURE 4.3 Solubility and diffusivity of various gases in natural rubber. (From Baker R.W., Blume I., *Chemtech.*, 16, 232, 1986. With permission.)

Transport through a dense polymer may be considered as an activated process, which can be represented by an Arrhenius type of equation. This implies that temperature may have a large effect on the transport rate. Equations 4.7 and 4.8 express the temperature dependence of the diffusion coefficient and solubility coefficient in Equation 4.5:

$$D = D_0 \exp(-E_d/RT) \quad (4.7)$$

$$S = S_0 \exp(-\Delta H_s/RT) \quad (4.8)$$

where

$E_d$  is the activation energy for diffusion

$\Delta H_s$  is the heat of solution

$D_0$  and  $S_0$  are temperature independent constants

By inserting Henry's law (Equation 4.6) into Fick's law (Equation 4.1), integrating across the membrane and remembering the definition of the permeability coefficient (Equation 4.5), Equation 4.2 was developed as the standard equation for transport through a dense polymeric membrane.

For gases in mixture, Equation 4.2 may be detailed out as in Equation 4.9:

$$J_i = \frac{P_i}{l} (p_h x_{i0} - p_l y_p) \quad (4.9)$$

where  $p_h$  and  $p_l$  denote pressure on feed side and permeate side, respectively. The fraction  $x_{i0}$  is the fraction of gas  $i$  on feed side, and depending on the design of the membrane module and flow regime for the gas, different calculation methods are adapted for this variable—details on this may be found elsewhere [1,28]. Parameters influencing the separation efficiency of polymers are elaborated on in Section 4.3.1.

#### 4.2.2 KNUDSEN DIFFUSION

Knudsen diffusion may take place in a microporous inorganic membrane or through pinholes in dense polymeric membranes. It may also take place in a mixed matrix membrane with insufficient adhesion between the phases.

Knudsen flow is characterized by the mean free path ( $\lambda$ ) of the molecules, which is larger than the pore size, and hence collisions between the molecules and the pore walls are more frequent than intermolecular collisions. A lower limit for the significance of the Knudsen mechanism has usually been set at  $d_p > 20 \text{ \AA}$  [28]. The classical Knudsen equation for diffusion of gas is

$$D_{Kn} = \frac{d_p}{3} \bar{v}_A = \frac{d_p}{3} \sqrt{\frac{8RT}{\pi M_A}} = 48.5 d_p \sqrt{\frac{T}{M_A}} \quad (4.10)$$

where

$d_p$  = average pore diameter (m)

$\bar{v}_A$  = average molecular velocity (m/s)

$M_A$  = molecular weight of gas component A (g/mol)

$T$  = temperature (K)

Hence for Knudsen diffusion, the square root of the inverse ratio of the molecular weights will give the separation factor. However, recent findings of Gilron and Soffer [29] indicate that the Knudsen mechanism can be significant for pore sizes as small as  $d_p \sim 5 \text{ \AA}$ . The Knudsen flow in this region takes on a slightly different form as indicated in the following expression derived as transport through a series of constrictions using resistance in series model:

$$D_{act, Kn} = g_d d_p \sqrt{\frac{8RT}{\pi M_A}} \exp\left(-\frac{\Delta E}{RT}\right) \quad (4.11)$$

Here  $g_d$  is the probability that a molecule can make a jump in the right direction given the jump length is  $d_p$  and the velocity is  $\bar{v}_A$ .

#### 4.2.3 SELECTIVE SURFACE FLOW

Selective surface flow is, as Knudsen diffusion, associated with transport through microporous membranes, usually inorganic materials. The mechanism of surface diffusion is disputed and several different approaches have been proposed in the literature.

Theories ranging from viewing the low surface coverage adsorbed gas as a 2D gas through a hopping model and into a more liquid like sliding layer exist. The mechanism dominating the surface diffusion coefficient will be influenced by a number of factors such as homogeneity of the surface, the temperature versus the adsorption enthalpy, and the surface concentration,  $c_s$  [30]. All three regimes can be described by a 2D analogue of Fick's law (Equation 4.1, given for a single component,  $a$ ). The flux,  $J_a$ , is now evaluated as molecules crossing a hypothetical line in the surface perpendicular to the direction  $x$ .  $D_s$  is the surface diffusion coefficient and  $dc_s/dx$  is the surface concentration gradient in the  $x$ -direction. The following expression may be used to determine if the surface transport is dominated by the 2D-gas model [30]:

$$q/RT < 1/a \quad (4.12)$$

where

$q$  is the adsorption enthalpy (J/mol)  
 $a$  is an energy fraction factor

The energy barrier for surface migration,  $E$ , is then defined as

$$E = aq \quad (4.13)$$

The 2D-gas is characterized by a surface mean free path,  $\lambda_s$ , inversely proportional to the surface concentration,  $c_s$ , and this  $\lambda_s$  value can be much larger than the spacing between adjacent surface sites.

If the  $q/RT$  part of Equation 4.12 is increased, then  $\lambda_s$  will no longer be controlled by collisions between adsorbed molecules. As  $q/RT$  increases,  $\lambda_s$  decreases and is approaching the spacing between adjacent sites, and a hopping mechanism is observed.

If the  $c_s$  is low then a random walk diffusion of independent molecules can be expected, and  $D_s$  would be given as

$$D_s = \frac{1}{4}\nu\lambda_s^2 \quad (4.14)$$

where  $\nu$  is the jump frequency factor, a factor which has a temperature dependence according to Arrhenius' law,  $\nu = \nu_0 \cdot \exp(-aq/RT)$  [1/s].

When  $c_s$  is increased, the chance of a molecule hitting another molecule increases and this interaction will bear some similarity to diffusion in liquid. Thus, the region of the sliding layer prevails. A more comprehensive discussion on this theory may also be found in Ref. [31].

Selective surface diffusion is governed by a selective adsorption of the larger (nonideal) components on the pore surface. The critical temperature,  $T_c$ , of a gas will thus indicate which component in a mixture is more easily condensable. The gas with the highest  $T_c$  will most likely be the fastest permeating component where a selective surface flow can take place. For a mixed gas an additional increase in selectivity may be achieved if the adsorbed layer now covering the internal pore walls restricts the free pore entrance so that the smaller nonadsorbed molecules cannot pass through.

#### 4.2.4 MOLECULAR SIEVING

Molecular sieving is the dominating transport mechanism when the pore size is comparable to the molecular dimensions, 3–5 Å; hence the smallest molecule will permeate, and the larger will be retained. The dimensions of a molecule are usually described with either the Lennard-Jones radii or the Van der Waal radii. For separation by molecular sieving, this is not a satisfactory way of stating the molecular size; a shape factor should also be included [9].

The sorption selectivity has little influence on the separation when molecular sieving is considered. An Arrhenius type of equation is still valid for the activated transport, but attention should be drawn to the pre-exponential term,  $D_0$  (see Equation 4.7). From transition state theory this factor may be expressed as shown in Equation 4.15 [32]:

$$D_0 = e\lambda^2 \frac{kT}{h} \exp\left(\frac{S_{a,d}}{R}\right) \quad (4.15)$$

where

$k$  and  $h$  are Boltzmann's and Planck's constants, respectively  
 $S_{a,d}$  is the activation entropy for diffusion  
 $e = g_d d_p$  in Equation 4.11

A change in entropy will thus have a significant effect on the selectivity when molecular sieving is considered. This is thoroughly discussed by Singh and Koros [9]. The flux may be described as in Equation 4.16 where  $E_{a,MS}$  is the activation energy for diffusion in the molecular sieving media.

$$J_a = \frac{\Delta p}{RTl} D_0 \exp\left(\frac{-E_{a,MS}}{RT}\right) \quad (4.16)$$

The selectivity for separation will normally decrease with increasing temperature because of increased diffusion rate for permeating components, and the sorption will be of minor importance.

#### 4.2.5 ION-CONDUCTIVE TRANSPORT

There are two important types of ion-conducting membranes for gas separation: (1) the proton ( $H^+$ )-conducting palladium membranes which are of great interest for combination with fuel cells and (2) the oxygen ion ( $O^{2-}$ )-conducting inorganic membranes, usually perovskite-type of oxides. Both are suitable for high temperature/high pressure applications, and an interesting feature is the 100% selectivity in favor of  $H_2$  and  $O_2$ , respectively.

##### 4.2.5.1 Proton-Conducting Membranes

Palladium and its alloys are recognized as very efficient proton-conducting membranes, which may be used for hydrogen separation and membrane reactor (MR) applications. The alloys are less apt to hydrogen embrittlement than pure Pd, and alloys with silver or copper represent the least expensive alternative of the alloys. These alloys also seem to produce membranes with enhanced chemical resistance (for instance toward  $H_2S$ ), additionally Pd–Ag alloys have a relatively higher  $H_2$  permeability than pure Pd. Efforts to produce economically viable Pd membranes have focused on preparing supported composite membranes with a thin dense Pd or Pd alloy layer. Forming this thin layer from two or more metals is quite challenging. The advantages of palladium membranes are especially the ability to separate out high-purity  $H_2$ , and that it may be used at high temperatures (300°C and above).

Hydrogen is present in many gas streams, being a product from dehydrogenation of hydrocarbons, a component in syngas or byproduct in bioprocesses. The basic flux equation for hydrogen,  $J_{H_2}$  (mol/m<sup>2</sup> s), is given in the following equation [33]. The flux for hydrogen atoms will be twice that of  $J_{H_2}$ :

$$J_{H_2} = -\frac{D_M}{2} \left( \frac{K_S(p_{H_2,ret}^n - p_{H_2,perm}^n)}{l} \right) \quad (4.17)$$

where

$D_M$  is the diffusion coefficient of a hydrogen atom in the metal (m<sup>2</sup>/s)

$K_S$  is the Sievert constant (mol/(m<sup>3</sup> Pa<sup>0.5</sup>))

For bulk transport of hydrogen,  $n = 0.5$  but approaches 1 for transport limited by surface kinetics. The exponent of 0.5 reflects the dissociation of the gaseous hydrogen molecule into two hydrogen atoms (protons) diffusing into the metal where an ideal solution of hydrogen in palladium is formed, then association again as  $H_2$  on the other side of the membrane. The hydrogen permeability of the palladium, here denoted as  $k$ , corresponds to the constants in Equation 4.17, expressed as in the following equation:

$$k = \frac{1}{2} D_M K_S \text{ (mol/m s Pa}^{0.5}\text{)} \quad (4.18)$$

Among the proton-conducting membranes Nafion or Nafion-like sulfonated perfluorinated polymers should also be mentioned. These materials are used for polymer electrolyte membrane (PEM) fuel cells, and in addition to being chemically very stable, they exhibit high proton conductivity at temperatures lower than 100°C. It is believed that permeability and thermal stability may be increased if tailor-made lamellar nanoparticles are added to a proton conducting polymer.

##### 4.2.5.2 Oxygen-Conducting Membranes

The zirconia and perovskite membranes may be considered as solid electrolyte membranes containing an oxygen ion conductor (various oxides). Depending on the type of materials used, the oxygen separation may take place according to direct excitation of the oxygen at several hundred degrees (gas separation controlled by electric current) or a mixed conductor method where the gas separation is proportional to  $\log(p_1/p_2)$ , the ratio of the partial pressures. (The reaction taking place at the electrodes is  $\frac{1}{2} O_2 + 2e^- \leftrightarrow O^{2-}$ , at the positive electrode the reaction is shifted to the left, at the negative electrode it is shifted to the right.) Detailed equations for transport can be found elsewhere [34,35].

### 4.2.6 FACILITATED TRANSPORT

Facilitated transport indicates that a carrier is introduced into the membrane matrix, usually a polymer matrix. This carrier will be selective for a certain gas component and enhance the transport of this component through the membrane.

The use of facilitated transport membranes for gas separation was first introduced by Ward and Robb [36] by impregnating the pores of a microporous support with a carrier solution, and a separation factor of 1500 was reported for CO<sub>2</sub>/O<sub>2</sub>. These membranes or supported liquid membranes (SLM) are discussed by several investigators, and initially very good separation properties are observed [37–40]. They are however known to have serious degradation problems like loss of carrier solution due to evaporation or entrainment with the gas stream, and the complexing agent (carrier) can be deactivated. These problems have restricted further development of SLMs. The use of ion exchange membranes as supports was proposed as an approach to overcome the problems of SLMs, and the application of ion exchange membranes for the facilitated transport of CO<sub>2</sub> and C<sub>2</sub>H<sub>4</sub> was first reported by LeBlanc et al. [41]. Since then a number of papers have been published on this type of membrane. Along with the use of ion exchange membranes as supports, another approach to overcome the above mentioned limitations was developed by introducing carriers directly into solid polymer membranes as illustrated in Refs. [42,43]. The FSC membranes have carriers covalently bonded to the polymer backbone, hence the carriers have restricted mobility, but are favorable when stability is considered. It is obvious that the diffusivity (and thus permeability) in an FSC membrane is lower than that of a mobile carrier membrane. The diffusivity of a swollen FSC-membrane should however show diffusivities between that of a mobile and a fixed carrier. Various ways of enhanced carrier transport have later been suggested [15,44,45]. It is suggested by many that CO<sub>2</sub> will be transported as carbonate or bicarbonate anions in anion-exchange membranes and as anions of various amines in cation-exchange membranes.

The characteristic of a facilitated or carrier-mediated transport is the occurrence of a reversible chemical reaction or complexation process in combination with a diffusion process. This implies that either the diffusion or the reaction is rate limiting: The total flux of a permeant A will thus be the sum of both the Fickian diffusion and the carrier-mediated diffusion as illustrated in Equation 4.19 [46]:

$$J_A = \frac{D_A}{l} (c_{A,0} - c_{A,l}) + \frac{D_{AC}}{l} (c_{AC,0} - c_{AC,l}) \quad (4.19)$$

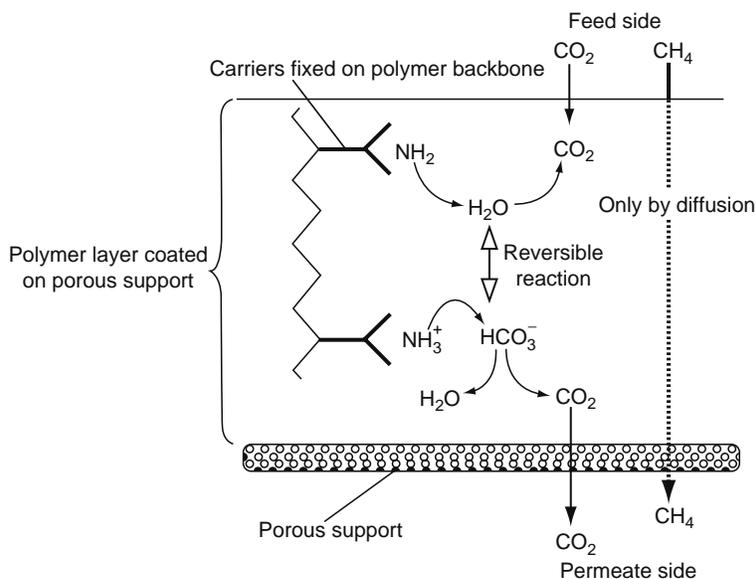

where the first term on the right hand side of the Equation 4.19 is the Fickian diffusion ( $D_A$ ), and the second term represents the carrier-mediated diffusion ( $D_{AC}$ ).  $l$  is the thickness of the membrane, while  $c$  (as defined by Henry's law, Equation 4.6) is the concentration of the component A and its complex AC at the interfaces of the membrane, and 0 and  $l$  indicate feed side and permeate side, respectively. The concentration difference of the complex AC in Equation 4.19 must be further expressed by an equilibrium constant of the complexing reaction and a distribution coefficient. This is given in detail by Cussler [46]. Nonpolar gases in a gas mixture will exclusively be transported through the membrane by Fickian diffusion, while by using partial pressures ( $p_A$ ) instead of concentration  $c_A$  (inserting Equation 4.6 into Equation 4.19), it can easily be seen that the driving force through the membrane will be the difference in partial pressures for the Fickian diffusion, and that transport also will depend on the solubility coefficient,  $S_A$ , for the gas in the polymer. For carrier-mediated transport (second term in Equation 4.19), the driving force will be the concentration difference of the complex AC through the membrane. The permeation of the nonpolar gases may additionally be hindered by polar sites introduced into the membrane matrix [15,44,45]. This should then lead to an increased permeance of the carrier-transported gas compared to ideal gases in the mixture (like CH<sub>4</sub>, N<sub>2</sub>, and O<sub>2</sub>), giving high selectivities in favor of the complexed gas (like for instance CO<sub>2</sub>). A proposed mechanism for facilitated transport for CO<sub>2</sub> in an FSC membrane is illustrated in Figure 4.4 [15].

## 4.3 MEMBRANE MATERIALS USED FOR GAS SEPARATION

To select the right membrane for a given gas separation is very challenging as the criteria are quite complex. The first choice is usually based on favorable flux and selectivity for a given gas mixture. Membrane performance will however have to be evaluated with respect to operating conditions as well as mechanical strength and durability. Finally, separation efficiency will have to be balanced against cost for each case evaluated. Choice of "the right membrane" may therefore have more than one answer. In this section properties for various materials available for gas separation membranes are discussed.

### 4.3.1 POLYMERIC MEMBRANES

Polymeric materials are still the most widely used membranes for gas separation, and for specific applications the separation technology is well established (see Section 4.6). Producing the membranes either as composites with a selective skin layer on flat sheets or as asymmetric hollow fibers are well-known techniques. Figure 4.5 shows an SEM picture of a typical composite polymeric membrane with a selective, thin skin layer of poly(dimethyl)siloxane (PDMS) on a support structure of polypropylene (PP). The polymeric membrane development today is clearly into more carefully tailored membranes for specific

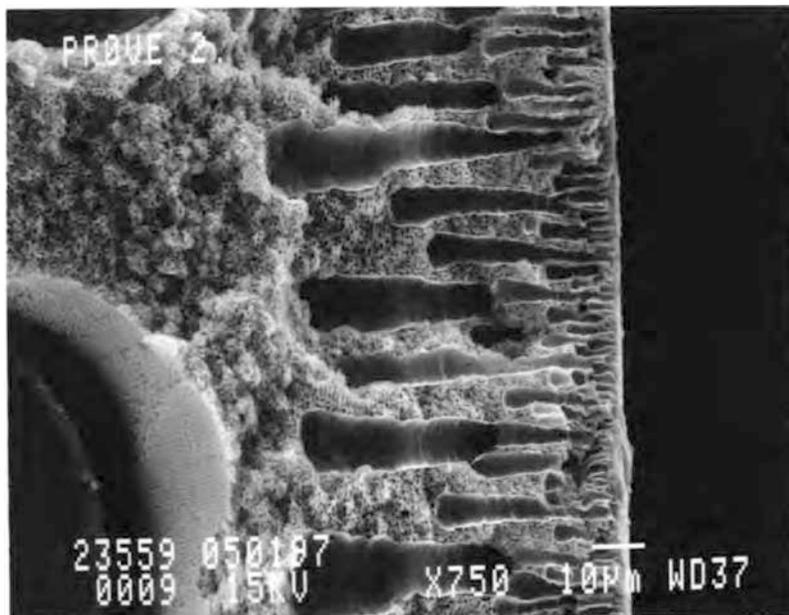

**FIGURE 4.4** A proposed mechanism of facilitated transport of CO<sub>2</sub> in an FSC membrane. (From Kim T.J., Hägg M.B., *J. Pol. Sci. Part B Polym. Phys.*, 42, 4326, 2004. With permission.)

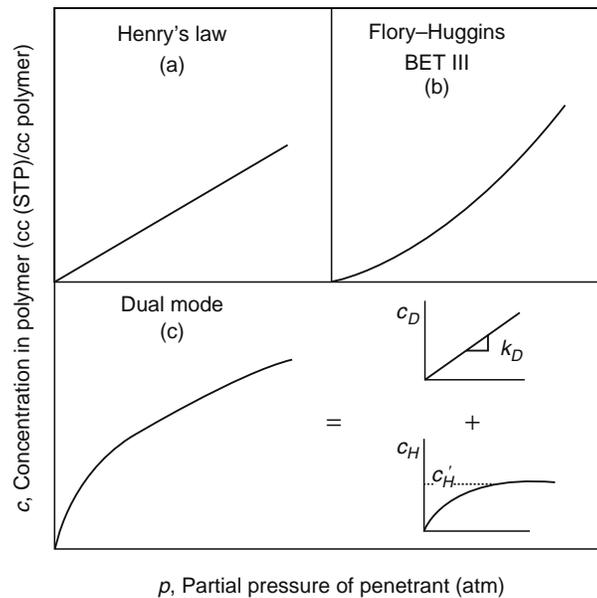

applications. The important material properties defining the separation performance are molecular structure, glass transition temperature ( $T_g$ ), crystallinity, degree of crosslinking, and as a function of these variables, durability with respect to possible degradation or loss of performance.

The basic transport mechanism through a polymeric membrane is the solution diffusion as explained in Section 4.2.1. As noted, there is a fundamental difference in the sorption process of a rubbery polymer and a glassy polymer. Whereas sorption in a rubbery polymer follows Henry’s law and is similar to penetrant sorption in low molecular weight liquids, the sorption in glassy polymers may be described by complex sorption isotherms related to unrelaxed volume locked into these materials when they are quenched below the glass transition temperature,  $T_g$ . The various sorption isotherms are illustrated in Figure 4.6 [47].

The solubility in glassy polymers is usually described by the so-called dual-mode model, which implies that there is a need for a more detailed definition of the sorption,  $c$ , in the flux Equation 4.1. Equations 4.20 and 4.21 illustrate this and can relate to

**FIGURE 4.5** SEM-picture of a typical composite membrane comprising of support structure of PP and a selective skin layer of PDMS.

**FIGURE 4.6** Typical gas sorption isotherms for polymers: (a) Henry's law illustrating ideal sorption as in a rubbery polymer where solubility is independent of concentration, (b) illustrating a highly nonlinear behavior according to Flory-Huggins; as can be expected for interactions between organic liquids or liquids with polymers (swelling results), and (c) illustrating the dual mode sorption (Langmuir) typical for a glassy polymer. (From Koros W.J., Chern R.T., *Separation of gaseous mixtures using polymer membranes*. In: Rousseau R.W., ed. *Handbook of Separation Process Technology*. John Wiley & Sons, New York, 862, 1987. With permission.)

Figure 4.6. The term  $c_D$  accounts for Henry's law, while  $c_H$  is the Langmuir term with  $b$  being the hole affinity constant ( $\text{bar}^{-1}$ ) and  $c'_H b$  is the saturation constant ( $\text{cm}^3 (\text{STP})/\text{cm}^3$ ):

$$c = c_D + c_H \quad (4.20)$$

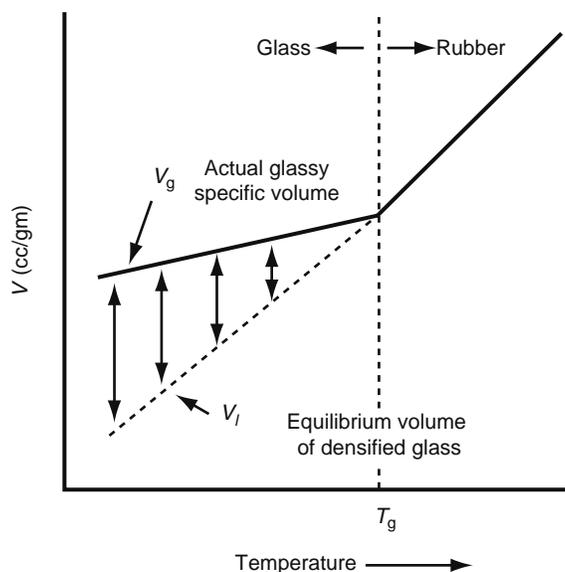

$$c = k_D p + \frac{c'_H b p}{1 + b p} \quad (4.21)$$

The dual-mode model has been extensively covered by several authors [25,47–49].

Figure 4.7 illustrates how the available free volume for transport increases with increasing temperature ( $V_f = V_T - V_l$ ), and the remarkable change when passing the  $T_g$  of a polymer [50]. According to the free volume diffusion model, the diffusion of molecules depends on the available free volume as well as sufficient energy to overcome polymer–polymer attractive forces. The specific volume at a particular temperature can be obtained from the polymer density, whereas the volume occupied at 0 K can be estimated from group contributions. Details on this theory may be found in relevant handbooks, textbooks, and numerous publications [25,48–52].

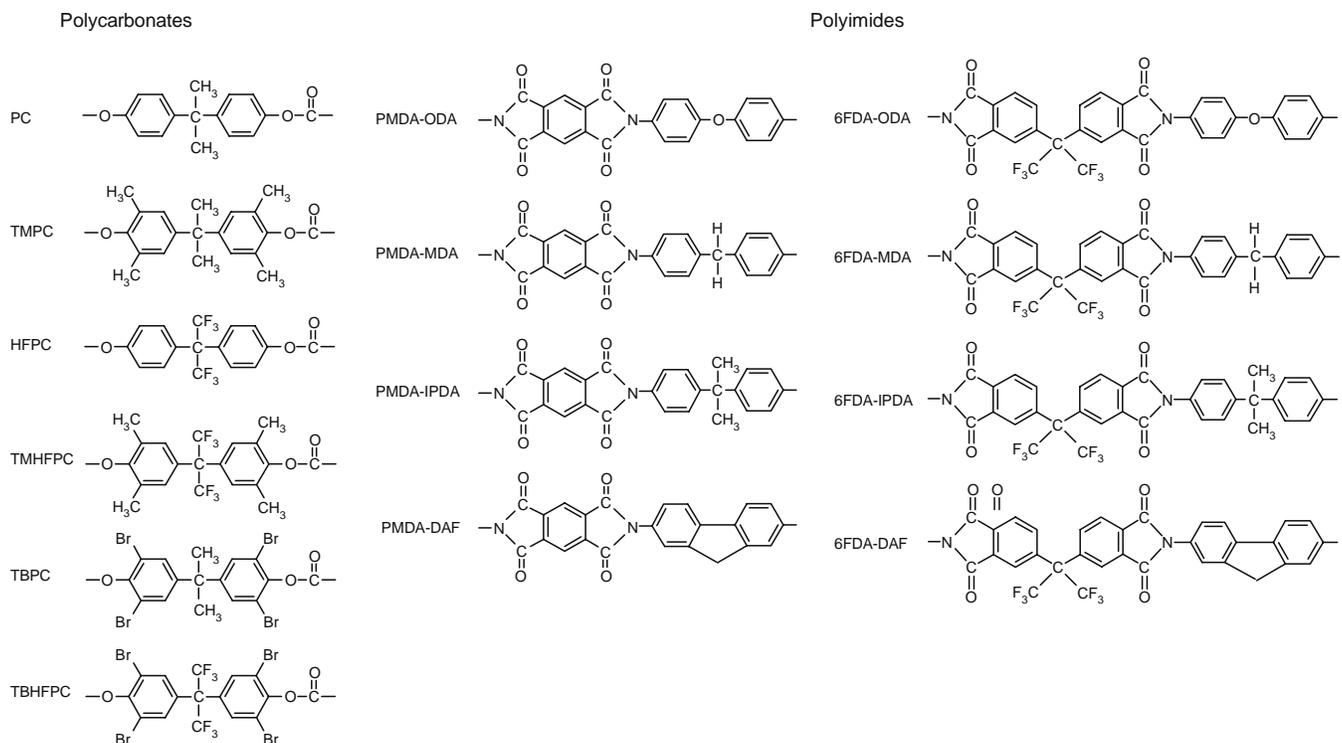

Nonideal gases dissolve more easily in polymers, and hence the separation factor may easily be in favor of a larger, nonideal gas component, compared to a small ideal gas. At the same time the nonideal component may swell the membrane, hence the net result is a decrease in selectivity. For a polymeric membrane, flux and selectivity are inversely related, hence a high flux usually means low selectivity. Elastomers have higher flux and lower selectivity for a given gas pair than a glassy material. This problem can be addressed by various methods: controlled crosslinking, opening the matrix by inserting carefully designed side groups to the main polymer chain, or functionalizing the polymer. Tables 4.2 and 4.3 illustrate how separation properties may be changed within two families of polymers by the change of side groups: polycarbonates [25,53] and polyimides [54].

Glassy polymers may swell in the presence of plasticizing agents, hence selectivities will be reduced and flux will be increased—the membrane loses performance. One way of avoiding this problem may be to incorporate cross-linkable functional groups in the polymer backbone. The crosslinking will be performed in the posttreatment process, and will hinder uncontrolled swelling. Regions of crystallinity and chemical crosslinking have somewhat similar effects on the transport properties of a rubber by causing restrictions of swelling and suppression of long-chain segmental motion. Transport in semicrystalline polymers is more complex due to tortuosity caused by the presence of the typically impermeable crystalline regions. Studies of gas sorption and transport strongly support the notion of the impenetrability of crystalline domains by even tiny gas molecules. The sorption coefficient seems to be essentially proportional to the volume fraction of amorphous material, while the effect on diffusion is more complex [25].

#### 4.3.1.1 Polymers Receiving Special Interest

The block copolymers form an interesting group of materials with promising separation properties for selected gas mixtures. These membranes usually combine the flexible phase of an elastomer with a dispersed phase of a glassy or crystalline polymer. The hard domains will act as physical crosslinks, and the temperature should not be raised above the  $T_g$  of the glassy polymer. Morphology and properties of the block copolymers are mainly determined by the  $A/B$  ratio and the size of the blocks. The separation mechanism in these membranes is typically based on sorption diffusion, but if correctly tailored, the sorption selectivity will be governing the separation. Examples that can be mentioned are copolymers of ethylene and vinyl alcohol. These two components are able to co-crystallize in the same crystal lattice, and the material can be tailored by varying the amount of the highly polar, diffusion-inhibiting vinyl alcohol component without strongly affecting the crystallinity [25]. Another example reported is block copolymers composed of polyamide (PA) and polyethylene glycol (PEG). In this material, the semicrystalline PA blocks will ensure the structural integrity while high molecular weight PEG will control the separation [55]. The permselectivity will typically be reverse, and these membranes may have a great potential for CO<sub>2</sub> capture or VOC removal from gas streams. Interesting results for CO<sub>2</sub>-H<sub>2</sub> separation (reverse selective) have been published by several authors [56,57].

The perfluorinated polymers are materials of special interest due to their exceptionally good chemical and thermal stability compared to other polymers. The challenge has however for many years been to prepare these materials with suitable gas separation properties. They used to be either very crystalline or too porous, hence selectivities were low. They may however be prepared as high flux—low selectivity membranes, which is acceptable for certain applications. Materials prepared from tetrafluoroethylene (TFE)

**FIGURE 4.8** Structure of Hyflon AD.

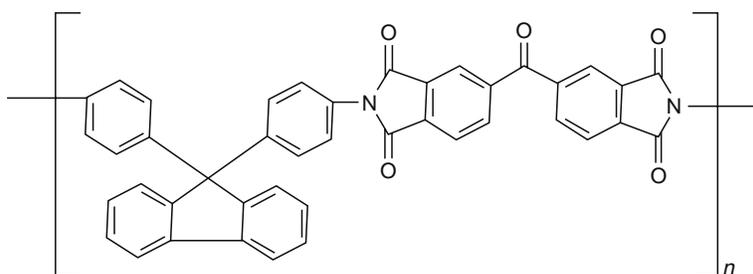

FIGURE 4.9 Example of structure of a cardopolymer based on polyimide.

and cyclic dioxole (TTD) are highly hydrophobic and have good potential for use in gas–liquid membrane contactors. The copolymer known commercially as Hyflon AD is made from TFE and TTD, and is an amorphous perfluoropolymer with glass transition temperature ( $T_g$ ) higher than room temperature. Hyflon AD 60 shows values of permeability and selectivity for gases that make the material interesting for separation—this was documented by Arcella et al. [58].

Kharitonov et al. [59] have shown that direct fluorination of the polyimide Matrimid is possible, hence the resulting membrane should have a nice potential for use in harsh environment. Perfluorinated materials were also studied by Hägg [60] for chlorine gas purification, and were shown to be exceptionally stable in these harsh environments. The selectivity was however too low. In a later publication on chlorine purification [31] it was suggested to use perfluorinated monomers as surface-modifying compounds for pore tailoring of glass membranes for chlorine gas separation.

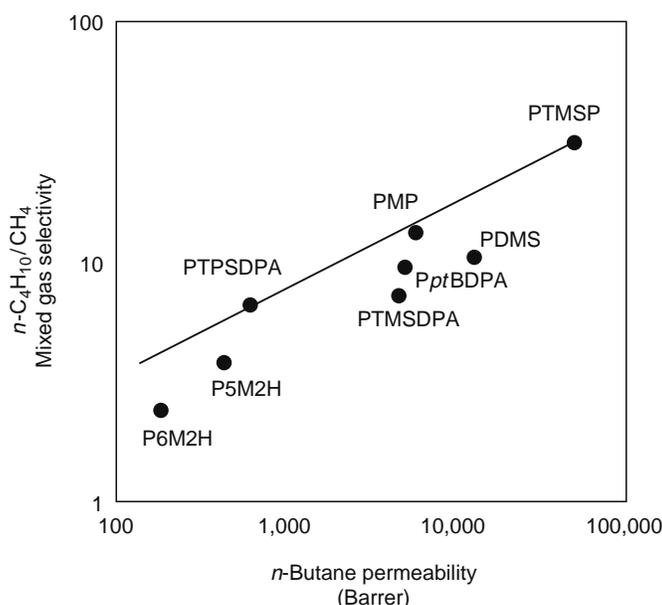

Hydrophilic perfluoromembranes may be prepared from TFE and copolymerized with perfluorosulfonylfluoridevinylether (SFVE), making a so-called Hyflon ion polymer, which is a rubbery polymer at room temperature. This polymer contains the group  $-\text{SO}_2\text{F}$  where F can be exchanged for a metal or hydrogen atom. This makes the material suitable for a wide variety of fields ranging from electrochemical electrolyzers (chloralkali and HCl), proton exchange fuel cells, energy storage, and electro dialysis to membrane catalytic reactors and many more applications [58].

The cardopolymers are polymers containing very bulky aromatic structure in the main chain. This structure can be coupled to a polyimide, polyamide, or polysulfone. Example of a cardopolymer based on polyimide is shown in Figure 4.9. The polymer may be further modified by substituting methyl groups or halogens into the aromatic rings. The bulky structure gives the polymers high gas permeability and high solubility for nonideal gases (like  $\text{CO}_2$  and hydrocarbons); they can be easily processed and are fairly heat stable. These materials have been extensively studied at Research Institute of Innovative Technology for the Earth (RITE) in Japan, and papers have been published documenting nice separation properties for  $\text{CO}_2/\text{N}_2$  ( $>35$ ) [61,62]. This makes the cardopolymers, especially the polyimide based, interesting for recovery of  $\text{CO}_2$  in flue gas. Takeuchi et al. [63] evaluated the costs of a global process of  $\text{CO}_2$  fixation and utilization using catalytic hydrogenation reaction, and converting  $\text{CO}_2$  to methanol. The recovered  $\text{CO}_2$  was then based on a membrane process using a cardopolymer.

The acetylene-based polymers have received new interest. These glassy polymers are amorphous and characterized by very high glass transition temperature (typically  $>200^\circ\text{C}$ ), high free volume, and very high gas permeabilities. The well-known poly(1-trimethylsilyl-1-propyne) (PTMSP) has the highest gas permeability of all known polymers. This polymer and other acetylene-based polymers show higher permeabilities to large condensable organic vapors than to small permanent gases [64], and PTMSP has the highest  $\text{C}_{2+}/\text{CH}_4$  and  $\text{C}_{2+}/\text{H}_2$  selectivities of any known polymer [65]. The selectivity of these gases is typically reverse compared to what is expected in a polymeric membrane. This can be understood by the large free volume in these polymers, and the high solubility of the hydrocarbons in the material. The transport may be described in the same way as the selective surface flow through a microporous membrane or a mixed matrix material (see Sections 4.3.2 and 4.3.3). Pinnau et al. [66], among others, have investigated the effects of the side-chain structure of substituted polyacetylenes on their gas permeation properties (see Figure 4.10).

#### 4.3.1.2 Fixed-Site Carrier Polymers

As an alternative to conventional polymeric membranes, facilitated transport membranes have attracted attention due to the potential of achieving both high permeabilities and high selectivities. Facilitated transport membranes may for instance selectively permeate  $\text{CO}_2$  by means of a reversible reaction of  $\text{CO}_2$  with incorporated complexing agent (carrier) in the membrane, whereas gases such as  $\text{H}_2$ ,  $\text{N}_2$ , and  $\text{CH}_4$  will permeate exclusively by the solution diffusion mechanism. As pointed out in Section 4.2.6, the ion exchange membranes were introduced as an approach to overcome the problems of SLMs, and the application of ion exchange membranes for the facilitated transport of  $\text{CO}_2$  and  $\text{C}_2\text{H}_4$  was first reported by LeBlanc et al. [41]. Since then a number of papers have been published on this type of membrane [67–70]. Along with the use of ion exchange membranes as supports, yet another approach to overcome the above limitations was developed by introducing carriers directly into polymer membranes [42,71,72]. These FSC membranes have carriers covalently bonded to the polymer backbone, hence the carriers have restricted mobility, but are favorable when stability is considered. It is obvious that the diffusivity (and thus

**FIGURE 4.10** Relationship between mixed gas  $n$ -butane permeability and  $n$ -butane/methane selectivity for a series of glassy polyacetylenes and rubbery PDMS. Feed pressure: 10 bar; permeate pressure: 1 bar; temperature: 25°C. (From Pinnau I., He Z., Morisato A., *J. Membr. Sci.*, 241, 363, 2004. With permission.)

permeability) in an FSC membrane is lower than that of a mobile carrier membrane. The diffusivity of a swollen FSC membrane should however show diffusivities between that of a mobile and a fixed carrier.

The aminated polymeric membranes for facilitated transport of CO<sub>2</sub> have been investigated extensively in recent years [69,73–75,15]. The findings of several of these investigators were that the aminated polymeric membranes showed higher permselectivity in water swollen condition than in dry condition—an ideal selectivity as high as 1000 for CO<sub>2</sub>/CH<sub>4</sub> was documented by Kim et al. [15]. Although promising, a mixed gas selectivity is, however, expected to show a significantly lower value. The anticipated mechanism for transport through the membrane is described in Section 4.2.6 and is illustrated in Figure 4.4. There has been a major increase in published papers and patents within the field of facilitated transport membranes during the period between writing and publishing of the current chapter; the author apologize for not having been able to incorporate these references.

The biomimetic membranes represent a special group of carrier membranes. They are artificial membranes based on biomembrane mimicking, i.e., imitation of the essential features biomembranes use for separation. Nitrocellulose filters impregnated with fatty acids, their esters, and other lipid-like substances may be used—in other words, an imitation of many nonspecific barrier properties of biomembranes. The transport of gas through these membranes will essentially be according to facilitated transport (see Section 4.2). Biomimetic membranes for CO<sub>2</sub> capture will transport the gas as HCO<sub>3</sub><sup>-</sup>. Development of these materials may be expected for selected applications.

### 4.3.2 CARBON MOLECULAR SIEVING MEMBRANES

The carbon molecular sieving (CMS) membranes are microporous carbon fibers or flat sheets prepared from carbonization of polymeric precursors under controlled conditions. Depending on the membrane pore size and the process conditions, the separation may take place according to (1) molecular sieving ( $d_p < 5 \text{ \AA}$ ), (2) selective surface flow ( $5 \text{ \AA} < d_p < 12 \text{ \AA}$ ), (3) Knudsen diffusion ( $d_p > 20 \text{ \AA}$ ), or combinations of these [6,29] (see Sections 4.2.2 through 4.2.4). The membranes for gas separation are prepared as hollow fibers or flat sheets. The hollow fibers may have the largest potential for becoming a successful separation unit on an industrial scale due to the possibility of making modules with a high packing density (m<sup>2</sup>/m<sup>3</sup>). The production process of these membrane modules is however challenging and expensive, and costs need to be brought down to be interesting for larger gas volume applications. The use of cheap polymeric precursors is favorable. Properties that should place the carbon membranes among the most promising membrane materials are their high temperature resistance and excellent chemical resistance to acids, hot organic solvents, and alkaline baths. The carbon membranes are fairly easy to produce as much is known about how carbonization conditions affect separation properties [6–11]. A carbon membrane can thus be tailored with a pore size giving excellent separation properties for a given gas mixture (high flux for permeating component and high selectivity for gas pairs).

The most serious disadvantages that have to be overcome or controlled are brittleness and the vulnerability of membranes to oxidizing agents and water vapor resulting in performance loss over time, hence regeneration is needed at intervals. When these effects are detected in the membrane performance, it is important to know how to address the problem (or preferably how to avoid it). It is important to know how to “open” pores which are blocked, how to regenerate the membrane, or how to optimize

separation performance by controlling the process variables. If basic knowledge about these membranes is not known to a user, he or she may very quickly draw the conclusion that CMS membranes are unstable, have too large a decrease in performance over time, and will probably judge them as “not suitable.” This may be very wrong. When used correctly, CMS membranes are promising candidates for gas separation and moderate volume gas streams.

The CMS membranes may be prepared in two different ways, and in both cases the pore tailoring is the focus for the final membrane:

1. By careful control of carbonization conditions; this is done by controlling heating rate, heating temperature, and choice of inert gas or vacuum during the process [76].
2. As explained in the patent of Soffer et al. [10], where microporous cellulose fibers are treated with CVD, and pores are tailored by postoxidation.

CMS membranes may also easily be functionalized, i.e., metals (like  $\text{AgNO}_3$ ,  $\text{MgO}$ ,  $\text{Fe}_2\text{O}_3$  or others) are imbedded in the structure of the precursor, and will enhance the separation for certain gas pairs.

A comprehensive review on carbon membranes has been given by Ismail and David [77].

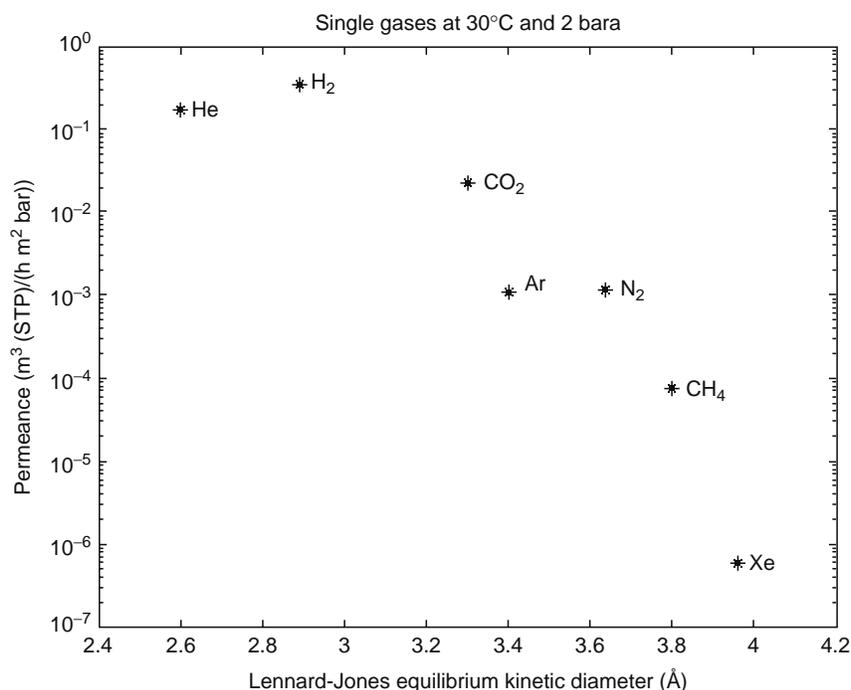

#### 4.3.2.1 Separation Properties for CMS Membranes

The ability of a microporous carbon fiber to separate gases depends on the pore size of the membrane, the physiochemical properties of the gases, and surface properties of the membrane pore. The pore size of a carbon fiber for gas separation is usually within the range of 3.5–10 Å, depending on the conditions for preparation of the membrane during carbonization or treatment afterward (postoxidation or chemical vapor deposition) [6–11]. With reference to the typical range indicated above for the transport mechanisms, one would expect that the dominating mechanisms will be either molecular sieving or selective surface flow.

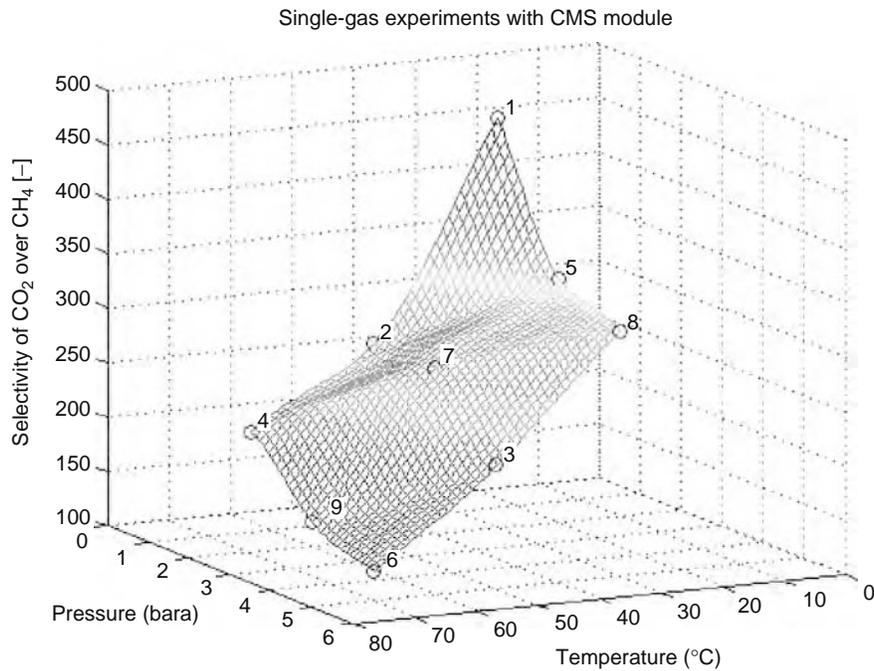

Figure 4.11 illustrates a carbon membrane with pores in the range suitable for molecular sieving [78]. As expected, there is a clear and indisputable correlation between flux and molecular size. In Figure 4.12, the carbon membrane is more open (pore size in the range 6–10 Å). The gas pair reported is  $\text{CO}_2$  and  $\text{CH}_4$ , and as can be seen, the selectivity is clearly in favor of  $\text{CO}_2$  indicating selective surface flow. The critical temperatures,  $T_c$ , and Lennard-Jones diameters,  $d_{L-J}$ , for the two gases are

$$\text{CO}_2: d_{L-J} = 3.94 \text{ \AA}, T_c = 304 \text{ K}$$

$$\text{CH}_4: d_{L-J} = 3.74 \text{ \AA}, T_c = 190.4 \text{ K}$$

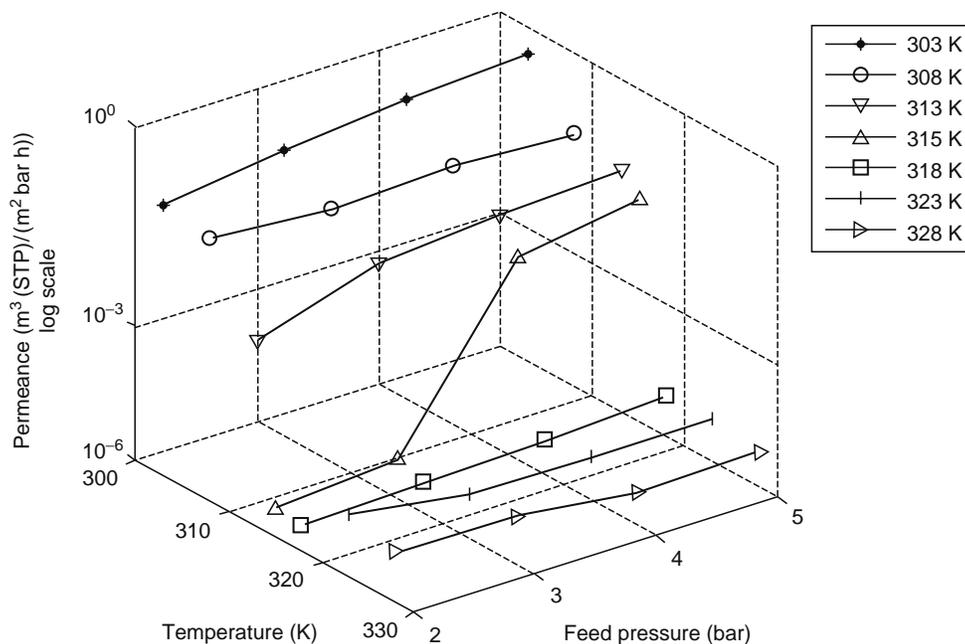

**FIGURE 4.11** Permeance as a function of L–J diameter for a sieving carbon membrane. (From Lie J.A., Synthesis, performance and regeneration of carbon membranes, Doctoral thesis NTNU 2005: 152, Trondheim, Norway, 2005. With permission.) Note: 1 [Å] = Ångstrom = 10<sup>-10</sup> m.

**FIGURE 4.12** Selectivity of  $\text{CO}_2/\text{CH}_4$  as a function of pressure and temperature for a CMS membrane. (From Lie J.A., Hägg M.B., Characterization of carbon membranes. Poster at The European Membrane Society's 20th Summer School, Trondheim, Norway, 2003. With permission.)

The easily condensable  $\text{CO}_2$  molecule will follow an SSF mechanism and seriously hinder  $\text{CH}_4$  to permeate, hence high selectivities are obtained.

Figure 4.13 illustrates the importance of finding the optimum process conditions (temperature, pressure) for the gas mixture to obtain maximum separation effect [79]. The diagram shows how the flux of propane changes with temperature and pressure. At  $\sim 3\text{--}4$  bar and 320 K, the flow changes from SSF to Knudsen diffusion. This “window” will vary for different gases, hence

**FIGURE 4.13** Permeance of propane as a function of pressure and temperature through a CMS membrane. (From Lie J.A., Synthesis, performance and regeneration of carbon membranes, Doctoral thesis NTNU 2005: 152, Trondheim, Norway, 2005. With permission.)

the optimum separation conditions can be found where the nonideal component will permeate according to SSF, and more ideal gases in the mixture, according to Knudsen flow.

#### 4.3.2.2 Regeneration

A CMS membrane will typically have a flux decline over time and regeneration will be necessary at intervals. Oxygen is one of the most detrimental species for a CMS membrane. When carbon materials are exposed to air at room temperature, irreversible chemisorption of oxygen may take place and C–O surface groups are formed [80]. These groups also provide sites of adsorption for H<sub>2</sub>O. Both phenomena will slightly reduce the effective size of micropores. The chemically bonded oxygen is only completely removed (as CO and CO<sub>2</sub>) by heating the sample to temperatures as high as 700°C–800°C with an inert gas.

Adsorption of water may result in flux decline as well. At low relative humidity, only active polar sites seem to be involved, and this sorption is so weak that the negative effect can easily be managed. With a high relative humidity (>25%), the negative effect may be substantial, caused by hydrogen bonding by neighboring water molecules forming clusters of adsorbed water [81]. It should be noted though that water uptake from various gases with same humidity level may differ greatly, and will therefore also be more or less easily removed.

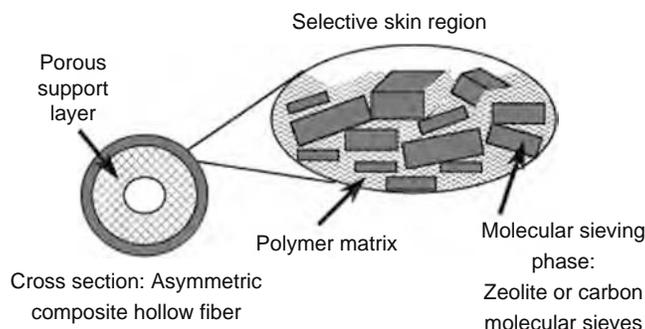

Adsorption of organics may cause the same type of flux decline. To recover a decreased membrane flux, three main approaches are reported:

1. The membrane may be treated at elevated temperatures, at least 200°C, under vacuum or inert atmosphere. If the flux is only partially restored after regeneration, this could be the result of incomplete removal of C–O surface groups.
2. If exposed to organics, treatment of the membrane with propene may be a good solution. Jones and Koros [82] found propene to be very effective in removing sorbed organics. In some cases the flux was completely restored—this was also confirmed by Hägg et al. [83].
3. The use of electrothermal regeneration (low voltage direct current) has successfully been tested out online [78].

#### 4.3.3 MIXED MATRIX MEMBRANES/NANOCOMPOSITES

Mixed matrix membranes (MMM) consist of a continuous polymeric phase wherein nanoporous or dense inorganic materials such as silica, zeolite, carbon particles/nanotubes are dispersed. The separation efficiency can be “tuned” by judiciously selecting the constituent materials (and their intrinsic properties), as well as the composition of the resultant nanocomposite. Molecular separation through the polymer occurs according to solution diffusion and is combined with surface diffusion or molecular sieving through the inorganic phase when a microporous filler is added (see Sections 4.2.1, 4.2.3, and 4.2.4). When dense fillers are added (silica, carbon nanoparticles), the membrane may become reverse selective, but still separate according to solution diffusion (see Section 4.3.3.2). The choice of polymer governs the application temperature range, and fabrication requires excellent adhesion between the filler and the polymer to avoid the formation of voids and, consequently, undesirable Knudsen diffusion [84]. Methods under current investigation to improve such adhesion rely on polymer softening (at temperatures near  $T_g$  or through the use of plasticizing agents) or reactive coupling with or without surface treatment of the filler.

The field of polymer nanocomposite membranes is developing rapidly due to the wide range of new properties that can be addressed within this unique class of materials. Resulting properties of these hybrid organic/inorganic materials (which differ significantly in property behavior) rely to a large extent on successful blending. Both enhanced thermomechanical properties and separation properties can be expected. The choice of polymers and inorganic fillers must be based on fundamental knowledge about separation properties as well as miscibility of the materials. For illustration of a mixed matrix membrane with microporous filler, see Figure 4.14 [85].

**FIGURE 4.14** Illustration of a mixed matrix membrane. (From Koros W.J., Mahajan R., *J. Membr. Sci.*, 175, 181, 2000. With permission.)

Robeson [4] showed that there exists a “trade-off” relationship between selectivity and permeability for dense polymer membranes. This plot was later updated by Singh and Koros [9] (see Figure 4.1). Molecular transport of light gases in such membranes typically occurs by a solution diffusion mechanism (as discussed in Section 4.2.1). For a polymer membrane to be commercially considered for the removal of CO<sub>2</sub> from H<sub>2</sub>, CH<sub>4</sub>, or air, both the CO<sub>2</sub> permeability and selectivity must be competitively high. Since the gases in the mixture with CO<sub>2</sub> often are smaller (H<sub>2</sub>) or about the same size as CO<sub>2</sub>, they may diffuse more rapidly through the polymers, and it follows that the diffusion selectivity ( $D_{\text{CO}_2}/D_{\text{gasB}}$ ) will be  $\leq 1$ . The only way to increase CO<sub>2</sub> permeability and selectivity simultaneously is thus to increase the solubility of CO<sub>2</sub> in the membrane. Such solubility enhancement is achieved by the introduction of chemical moieties (nanofillers) into the polymer to promote the permeation flux of CO<sub>2</sub> by increasing the free volume, or by using physically modified polymer nanocomposites (molecular sieving materials) suitable for adsorption flow. Both result in a mixed matrix membrane. Examples of porous nanofillers are carbon molecular sieves; examples of nonporous nanofillers are fumed silica and carbon black.

#### 4.3.3.1 MMM: Polymer with Carbon Molecular Sieves

Mixed matrix membranes with molecular sieves incorporated combine the high separation capacity of molecular sieving materials (see Section 4.3.2) with the desirable mechanical properties and economical processing attributes of polymeric materials.

Vu et al. [86] incorporated CMS materials into polymers to form mixed matrix membrane films for selective gas separations. The CMS, formed by pyrolysis of a polyimide precursor and exhibiting an intrinsic CO<sub>2</sub>/CH<sub>4</sub> selectivity of 200, was dispersed into a polymer matrix. Pure-gas permeation tests of such MMMs revealed that CO<sub>2</sub>/CH<sub>4</sub> selectivity enhanced by as much as 40%–45% relative to that of the pure polymer. The effective permeabilities of fast-gas penetrants (e.g., O<sub>2</sub> and CO<sub>2</sub>) through these MMMs are also improved relative to the intrinsic permeabilities of the unmodified polymer matrices. For a CO<sub>2</sub>/H<sub>2</sub> gas mixture, the CO<sub>2</sub> will serve as the fastest permeating component, and H<sub>2</sub> will be retained on the feed side to avoid repressurization, in which case the polymer matrix dictates the minimum membrane performance. Properly selected molecular sieves can only improve membrane performance in the absence of defects. The polymer matrix must be chosen so that comparable permeation occurs in the two phases (to avoid starving the sieves) and so the permeating molecules are directed toward (not around) the dispersed sieve particulates. The molecular sieve must be selected so that its pores can separate the gas molecules of interest according to size. In the case of CMSs, varying the carbonization conditions during fabrication controls the pore size. This is an advantage of CMS membranes over zeolitic molecular sieves, in which the pore size is fixed for a given zeolite type.

#### 4.3.3.2 MMM: Polymer with Nonporous Nanoparticles

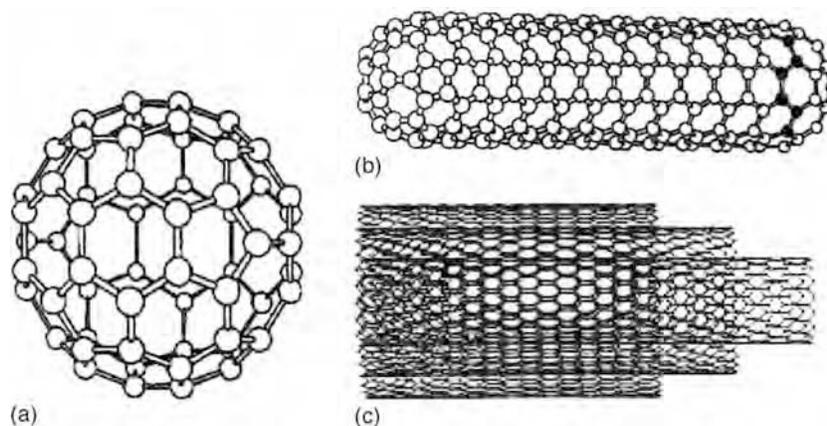

Nanoscale inorganic fillers will affect the local chain packing, which affects the local free volume, and hence the molecular transport of permeating species. The polymer may be a rigid-chain polymer or a self-organized block copolymer. If the dispersed filler in MMMs consists of a nonporous material (e.g., carbon nanotubes, fumed or colloidal silica), the nanoscale particulates may disrupt the packing of the polymer chains, if they are rigid, and consequently increase the accessible free volume in the polymer matrix. This increased free volume augments molecular diffusion and weakens the size-sieving nature of the polymer, thereby increasing both permeability and reverses the selectivity. Since permeability depends on diffusivity and solubility, these MMMs will favor permeation of the larger (and more soluble) components through the membrane. The introduced nanoparticles may also alter the mechanism by which a copolymer self-organizes, hence influencing the equilibrium morphology and polymer thermodynamics (and then properties).

Merkel et al. [87] mixed a substituted polyacetylene, poly(4-methyl-2-pentyne) (PMP), with fumed silica particles possessing hydrophobic trimethylsilyl surface groups. Dispersion of the particles was achieved by matching the polarity of the polymer and the particle surface groups, as well as by controlling film-drying conditions. Addition of fumed silica (up to 30 vol %) (size ~10 nm) promoted a considerable increase in the permeability of CH<sub>4</sub> relative to that of pure PMP. In Figure 4.15 various forms of carbon molecules are illustrated [88]. Fullerenes generally refer to the entire class of closed spheroidal aromatic molecules consisting of only carbon atoms, up to 600 atoms.

#### 4.3.4 INORGANIC MEMBRANES

The inorganic membranes had until the late nineties received fairly little attention for applications in gas separation. This has mainly been due to their porous structure, and therefore lack of ability to separate gas molecules. Within the group of inorganic membranes there are however the dense metallic membranes and the solid oxide electrolytes; these are discussed separately in Section 4.3.5. With reference to Section 4.2, the possible transport mechanisms taking place in a porous membrane may be summarized as in Table 4.4 below, as well as the ability to separate gases (+) or not (–). Recent findings [29] have however documented that activated Knudsen diffusion may take place also in smaller pores than indicated in the table.

The increasing interest in inorganic membranes for gas applications is undoubtedly due to their excellent high temperature resistance. Inorganic membrane reactors (including carbon membranes) may thus have a very nice potential for industrial

**FIGURE 4.15** Schematic illustration of different nanostructured carbons. (a) A C60 fullerene, (b) A single-wall carbon nanotube, and (c) a multi-wall carbon nanotube. (From Kroto H.W., Heath J.R., O’Brian S.C., Curl R.F., Smalley R.E., *Nature*, 318, 162, 1985. With permission.)

applications. The various configurations of membrane reactors are however not discussed in this chapter. Their separation properties may be understood on the basis of the materials used, kinetics, and process conditions.

Porous materials have very complex structure and morphology, and parameters like porosity, pore size distribution, and pore shape are extremely important variables affecting gas separation properties. A schematic of different pores is given in Figure 4.16 [89]. As can be seen, pore constrictions, dead-end pores, and interconnection between pores will contribute to the characterization of the membrane, hence the tortuosity ( $\tau$ ) plays an important role. The tortuosity will have a value equal to unity ( $= 1$ ) for a cylindrical pore. The inorganic membranes may be symmetric or asymmetric. The symmetric membranes are systems with a homogenous structure throughout the membrane. Capillary glass membranes and anodized alumina membranes are examples within this group. In most cases however the inorganic membranes are asymmetric with a composite structure consisting of several layers with a gradual decrease in pore size to the feed side. Examples are ceramic aluminas synthesized by the solgel technique or carbon–zirconia membranes. For gas separation, surface-modified inorganic membranes have become increasingly important. An introduction to the synthesis and properties of inorganic membranes may be found in comprehensive textbooks [11,90,91].

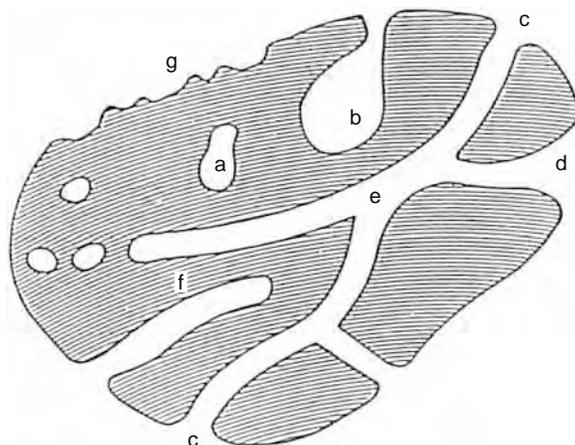

#### 4.3.4.1 Modified Inorganic Membranes

As illustrated in Table 4.4, the pore size of a microporous inorganic membrane has to be brought down in order to separate gases. Only for pore sizes in the range below Knudsen flow, the separation may be efficient and follow either selective surface flow or capillary condensation. Separation according to configurational diffusion may take place if the pore size is sufficiently small ( $<1$  nm). The surface may also be modified to change its chemical nature and thus separation properties. Several ways of modifying the surface structure of ceramic membranes have been suggested by Burggraaf and Keizer [90], and pore sizes  $<1$  nm have been obtained (see Table 4.5). The main questions related to economy of production and brittleness of these

membranes are still to be solved although the materials may show excellent separation properties for selected gas mixtures, especially in the range of selective surface flow.

Effects of temperature and pressure will play an important role for the resulting separation. This has been discussed for different MFI zeolite membranes by Posthusta et al. [92].

A usually less expensive way for surface modification is using organic compounds. The range for application will then be determined by the decomposition temperature of the organic compound. Several papers have been published reporting promising results for separation [93,94]. The glass membranes (silicate membranes) should be especially mentioned since they have proved to be exceptionally resistant to aggressive gases like chlorine and hydrochloric acid [60,95], and have a nice potential for separation of such gases when membranes are surface modified with chemically resistant perfluoro compounds [31].

### 4.3.5 ION-CONDUCTING MEMBRANES

#### 4.3.5.1 Proton-Conducting Pd Membranes

For the transport of hydrogen through a palladium membrane, please refer to Section 4.2.5.1. The membranes may be prepared as pure palladium membranes, but the trend has moved in the direction of preparing composites and using Pd alloys. There seems to be a number of advantages using composite palladium membranes supported on porous substrates over palladium foils

<sup>a</sup> a-TiO<sub>2</sub>: anatase titania.

and tubes—one important aspect is the stability of the system as stability problems increase with a reduction in thickness [96]. Stability is also alloy dependent. The porous supports used comprise porous alumina or glass, and porous metals including porous Ni and porous stainless steel. However, from an industrial perspective, alumina supports have disadvantages in terms of insufficient sealing and difficult fabrication of large modules. (This is often a general problem with inorganic membranes for gas separation.)

There are various techniques for the deposition of Pd or its alloys on a support; details on this may be found elsewhere [96,97]. Among these methods, electroless plating is quite attractive due to the possibility of uniform deposition on complex shapes and large substrate areas, hardness of deposited film, and very simple equipment. The main advantage of Pd alloys compared to pure Pd for use in hydrogen separation and MR applications is that Pd alloys have a reduced critical temperature for the  $\alpha$ - $\beta$  transition, and may therefore be operated in the presence of hydrogen at temperatures below 300°C without risking the hydrogen embrittlement observed for pure Pd membranes [98]. The components most used in the Pd alloys are silver (Ag) or copper (Cu) added in a weight percentage up to around 30.

The palladium–silver alloys have attractive enhanced permeability compared to pure Pd while the palladium–copper alloys are more resistant to sulfur. The hydrogen flux through a 20  $\mu\text{m}$  thick palladium membrane was measured by Mardlovich et al. [97] at 350°C to be between 2 and 2.5  $\text{m}^3/\text{m}^2 \text{h}$ , while the performance of palladium–copper alloy membranes over a wide range of temperatures and pressures is presented by Howard et al. [99]. Coexisting hydrocarbons in the gas stream may influence hydrogen permeation through palladium membranes. It has been documented that especially propylene in the gas mixture may seriously affect hydrogen permeation [100]. Propylene decomposes and the carbonaceous matter forming would chemisorb to the membrane surface. Regeneration with pure hydrogen at high temperature (600°C) may however restore the flux. Other components of concern that may cause deactivation and poisoning of a palladium membrane are CO, H<sub>2</sub>O, H<sub>2</sub>S, and Cl<sub>2</sub>.

The very attractive feature of palladium membranes and its alloys is clearly the favorable selectivity for hydrogen permeating at high temperatures. This makes the membranes attractive for use in fuel cells.

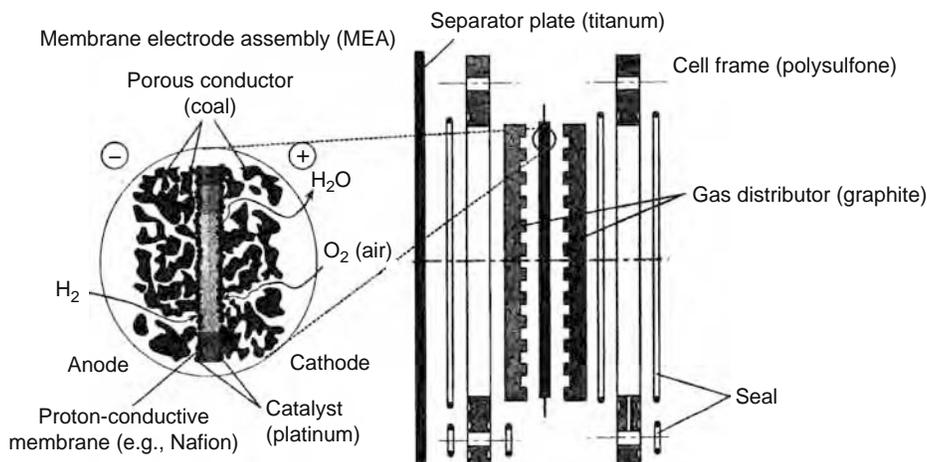

#### 4.3.5.2 Proton-Conducting Polymeric Membranes

Many different kinds of fuel cells are presently known, most of them suitable for high-temperature applications—for details see Ref. [101]. The polymeric proton-conducting membranes (polymer electrolyte membranes; PEM) are however suitable for low temperature operations (<100°C) and have the advantage of low weight.

In a fuel cell, electricity is produced by an electrochemical reaction. The proton is produced at the anode by oxidation of the fuel, and will diffuse through the proton-conducting membrane to the cathode where water is formed (see Figure 4.17). The fuel may be hydrogen or hydrogenated molecules. When hydrogen is used as fuel, the PEM fuel cells will use Nafion or Nafion-like sulfonated perfluorinated polymers. These materials have high proton conductivity combined with high stability. For more details on these membrane please see Refs. [101,102].

#### 4.3.5.3 Oxygen-Conductive Membranes

Industry is continuously in search for suitable membrane materials which may produce high purity oxygen at low cost and preferably at low temperature. This type of material is yet to be developed. Presently the zirconia and perovskite membranes

**FIGURE 4.17** Transport through a fuel cell. (From Cappadonia M., Stimming U., Kordesch K.V., de Oliveira J.C.T., Fuel cells. In: *Ullmann's Encyclopedia of Industrial Chemistry*. Vol. 15. 6th ed. Wiley-VCH, Weinheim, Germany, 95, 2003. With permission.)

may be used to produce pure oxygen at high temperatures as these materials (solid electrolytes) contain an oxygen ion conductor. When used as an MR, the permeating oxygen may be used for oxidation of ethane on the permeate side, hence producing syngas [103]. (For details on the transport, see Refs. [34,35].)

Air Products and Chemicals Inc. presented recently a ceramic oxygen-transporting membrane operating at high temperature (transporting  $O_2^-$ ). The material is a mixed-conductor where both oxygen ions and electrons are highly mobile within the solid. The technology makes use of an oxygen partial pressure gradient across the ceramic membrane to drive the oxygen flux [13]. The technology is suited for advanced power generation that requires oxygen for combustion or gasification.

#### 4.4 MODULE DESIGN

Depending on the type of materials to be used for membrane separation, the module may have different configurations. The footprint of the membrane separation unit may be an important issue where it is going to be placed, and packing density of the module ( $m^2/m^3$ ) will then have to be considered. Some modules may be suitable for large-volume applications, some for smaller. In most cases investment cost and lifetime of the membrane will decide which one should be chosen. If specific process conditions are necessary for optimum performance of the membrane (pressure, temperature, filtering, and drying of gas), required utilities must be included in cost estimation.

For calculation of required membrane permeation area, flow patterns for the various module designs must be considered. The cross-flow, counter-current, cocurrent, or complete mixing flow will result in different degrees of purity for the same stage cut,  $\theta$  ( $= q_p/q_f$ ). This is illustrated in Figure 4.18 below [104].

The basic equations for flux and selectivity are given in Section 4.2. Inserting the relevant flux equation for  $J_i$  into Equation 4.22 below, the required membrane permeation area,  $A_m$ , may be calculated:

$$A_m = q_{p,i}/J_i \quad (4.22)$$

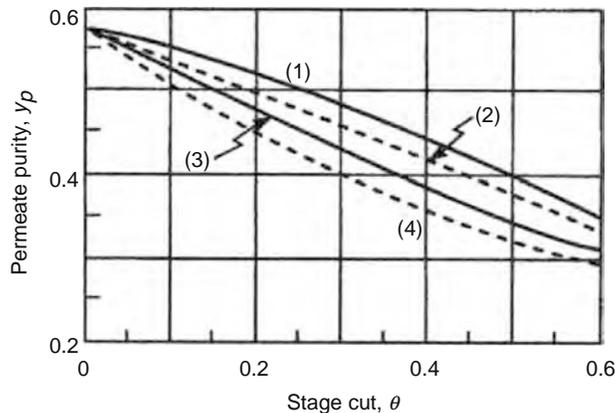

where

$q_{p,i}$  is the permeation rate ( $m^3$  (STP)/h) of component  $i$

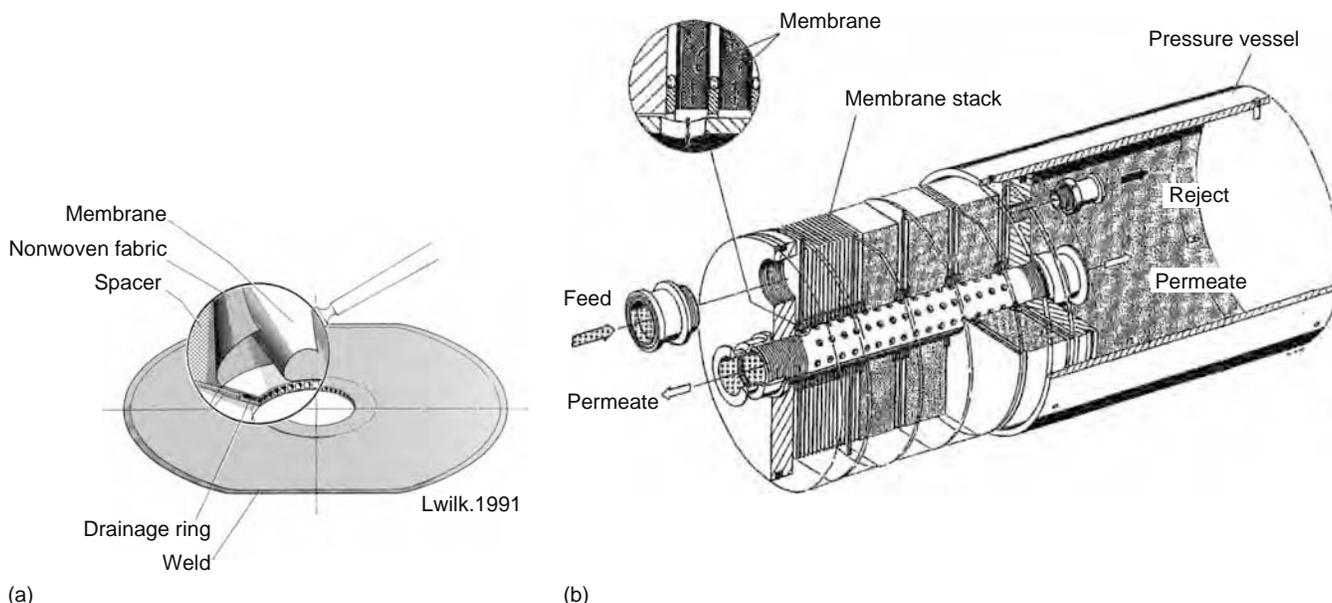

$J_i$  the flux ( $m^3$  (STP)/ $m^2$  h)

In a real case there are several additional variables to be taken into account: possibility of concentration polarization, pressure drop, heat transfer, and Joule–Thomson effect across the membrane. The J–T effect may be significant when there is a large  $\Delta P$  across the membrane and with nonideal gases permeating. Fugacities should then be used in the calculations. These effects are discussed by several authors [105,106].

The standard module configurations are presented below. With the development of new membrane materials for various applications (as discussed in Section 4.3), new configurations for optimum gas separation may be expected on the market in the future.

**FIGURE 4.18** Effect of stage cut  $\theta$ , and flow pattern on permeate purity. Operating conditions (air) are as follows:  $x_{f,O_2} = 0.21$ ,  $\alpha^* = 10$ ,  $p_h/p_l = 5$ ,  $P_{O_2} = 500$  Barrer. Line (1) is counter-current flow, line (2) is cross-flow, line (3) is cocurrent flow, and line (4) is complete mixing. (From Walawender W.P., Stern S.A., *Sep. Sci.*, 7, 553, 1972. With permission.)

**FIGURE 4.19** The Borsig envelope-type membrane module. (From Ohlrogge K., In: Final Report for EU-project BE97-4589. Dehydration and dewpointing of natural gas by membrane technology. GKSS, Germany, 2002. With permission.)

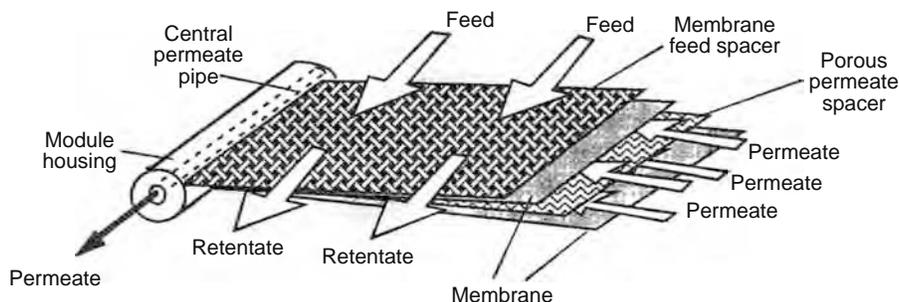

#### 4.4.1 FLAT SHEET PLATE AND FRAME/Envelope Type

Inorganic or metallic membranes for gas separation are usually prepared as discs or flat sheets. These thin sheets or discs may be quite vulnerable to breakage, and to assemble the membranes in modules is quite challenging. These membranes are usually intended for high-temperature gas applications, and sealing technology may be complicated. Carbon membranes are also facing this challenge at high temperatures.

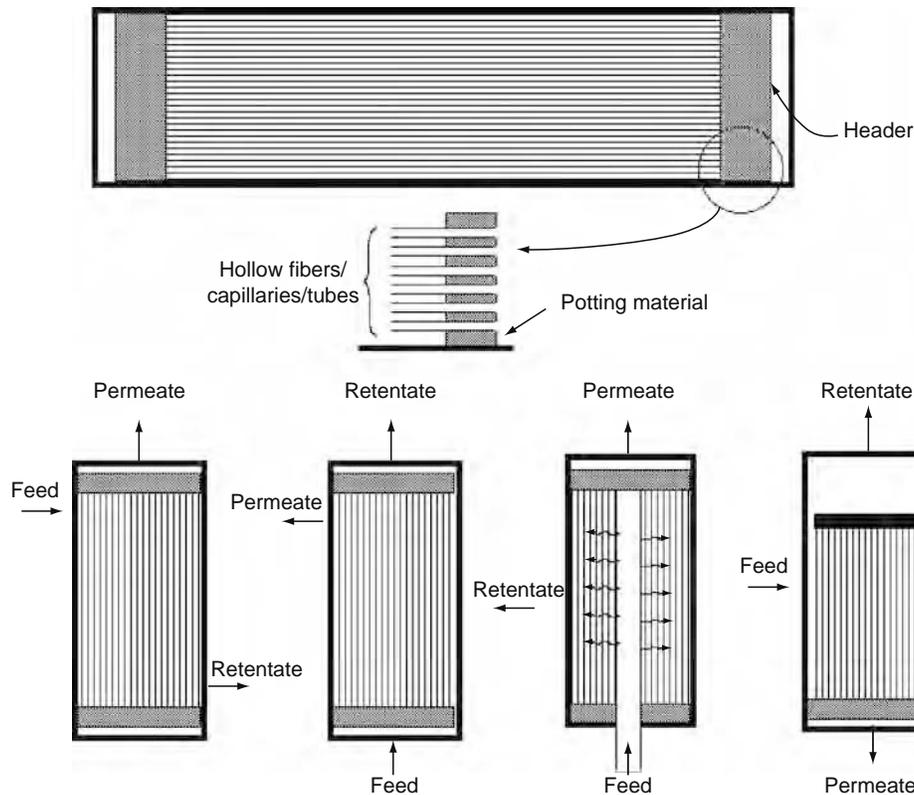

Polymeric flat sheet membranes are easy to prepare, handle, and mount. For gas separation, the flat sheet membranes are composites with a selective polymer coated on a support. A commercial configuration that has been quite successful for hydrocarbon vapor recovery is the Borsig envelope type module (see Figure 4.19) [107]. Packing densities for flat sheet membranes may be in the range of 100–400 m<sup>3</sup>/m<sup>2</sup> [1].

#### 4.4.2 SPIRAL-WOUND MEMBRANE

The typical spiral-wound membrane, as shown in Figure 4.20, consists of four layers wrapped around a central collection pipe: membrane, spacer (providing a permeate channel), membrane, and a new spacer (providing a feed channel). The feed-side spacer acts as a turbulence promotor, whereas on the permeate side the flow is directed toward the central pipe. The spiral-wound membrane will typically be a polymeric composite material, and is much used also for liquid separation. The packing density of this type of module will depend on the channel height, but is usually within the range of 300–1000 m<sup>2</sup>/m<sup>3</sup> [1]. Several modules may be assembled in one pressure vessel.

**FIGURE 4.20** A spiral wound membrane module. (From Mulder M., *Basic Principles of Membrane Technology*. 2nd ed. Dordrecht, Kluwer Academic Publishers, 1996. With permission.)

**FIGURE 4.21** Hollow fiber membrane modules with different configurations. (From Pellegrino J., Sikdar S.K., Membrane Technology, Fundamentals of Bioremediation [http://membranes.nist.gov/Bioremediation/fig\\_pages/f5.html](http://membranes.nist.gov/Bioremediation/fig_pages/f5.html) (accessed September 2004). With permission.)

#### 4.4.3 HOLLOW FIBER MEMBRANES

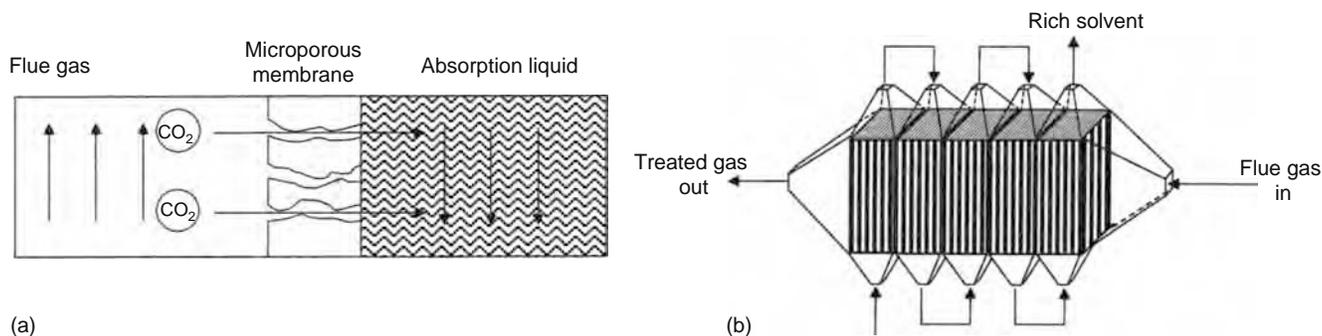

The hollow fiber membranes are the optimum choice for gas separation modules due to their very high packing density (up to  $30,000 \text{ m}^3/\text{m}^2$  may be attained [1]). Figure 4.21 shows alternative configurations for such modules [108]. Modifications of this configuration exist, where possibility for introduction of sweep gas on permeate side is included, or fibers may be arranged transversal to the flow in order to minimize concentration polarization [109,110]. The hollow fiber membranes are usually asymmetric polymers, but composites also exist. Carbon molecular sieve membranes may easily be prepared as hollow fibers by pyrolysis.

#### 4.4.4 MEMBRANE CONTACTORS

A membrane contactor may be considered as a new unit operation where the membrane acts as a barrier between a gas and a liquid phase. The most important advantages of a membrane contactor compared to a traditional absorber are (1) reduction in size and weight (important when used offshore), (2) with the gas and liquid separated by a barrier, the liquid and gas flow rate may be adjusted independently, (3) no entrainment, flooding, or channeling, and (4) reduction in solvent loss. The membrane contactor may have different module configurations, an illustration of the Aker Kvaerner membrane contactor is shown in Figure 4.22 [111]. A different design is presented by Liqui-Cel [112]. Only the component to be removed from the gas mixture will be able to diffuse through the membrane and into the selective liquid absorbent. A typical example is the removal of  $\text{CO}_2$  from a gas stream using an amine absorbent on the liquid side. Factors like pore size, pore size distribution, hydrophobicity, and hydrophilicity of the membrane will play a major role in order not to have breakthrough of gas or liquid across the membrane. Membrane-based absorption and desorption is widely used and studies are reported in several papers [113–117].

The governing equation to avoid breakthrough is the LaPlace equation as shown in the following equation:

$$r_p = \frac{2\gamma}{\Delta P} \cos \Theta \quad (4.23)$$

**FIGURE 4.22** Illustration of the principle for removal of CO<sub>2</sub> from a gas stream (left) using a membrane contactor with hollow fibers (right). (From Hoff K.A., Modeling and experimental study of CO<sub>2</sub> absorption in a membrane contactor. Thesis NTNU, Trondheim, 2003. With permission.)

where

- $r_p$  = pore radii
- $\gamma$  = surface tension at liquid/gas interface (N/m)
- $\theta$  = contact angle

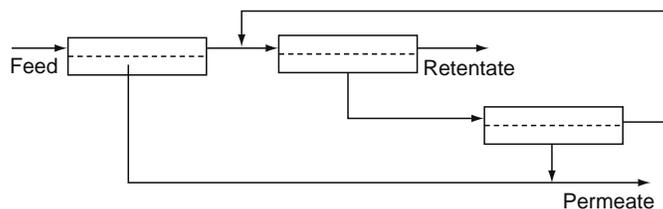

#### 4.4.5 SYSTEM DESIGN

Quite often a single stage membrane unit cannot give the desired product quality, and the product may be either the permeate or retentate. A cascade solution may then be a viable option where a fraction of permeate streams are being recompressed and recycled, membrane units are placed in combinations of series or parallel, or permeate streams are being fed to a second stage for further permeation. These calculations will very quickly become quite complicated, and should preferably be performed with an integrated membrane simulation tool hooked up to a standard simulation program (like Hysys, ProII, or Aspen). Relevant papers for design of the gas separation process design may be found in Refs. [28,118,119]. Figure 4.23 illustrates a three stage separation unit typically developed for separation of CO<sub>2</sub> from CH<sub>4</sub> (natural gas) [120].

### 4.5 CURRENT APPLICATIONS AND NOVEL DEVELOPMENTS

As already mentioned, most of the membranes used in gas applications today are still the polymeric solution diffusion materials, and among these, the glassy materials separating according to molecular size are dominating the market. This will probably change when new tailor-made materials (see Section 4.2) are commercialized. For all membrane applications the gas mixture and process conditions (volumes, pressures, temperature, specifications of product for purity) will be governing the choice of membrane material and module design.

The dominating processes for industrial membrane applications are still production of high purity nitrogen, recovery of hydrogen from gas streams, and recovery of carbon dioxide. With respect to both hydrogen and CO<sub>2</sub>, a major increase in membrane applications may be expected with the development of tailor-made materials and with the focus worldwide on renewable energy and emission of greenhouse gases. The removal of volatile organic compounds (VOCs) is also a major potential area for membrane applications due to environmental concern and international agreements on reduction of emissions. There is only a selection of about 8–9 materials used for 90% of the total gas separation membranes today [121]. An overview of commercial-scale membrane suppliers is presented in Table 4.6, adapted and updated after Spillman by Zolands and Fleming in 2001 [122].

**FIGURE 4.23** A three stage membrane separation process—the recycled gas from stage three need to be recompressed. This configuration could typically be used for removal of CO<sub>2</sub> from gas stream where the retentate is the product. (From Spillman R.W., *Chem. Eng. Progr.*, 85, 41, 1989. With permission.)

#### 4.5.1 HYDROGEN RECOVERY

Hydrogen is typically being recovered from gas streams at refineries (from hydrocrackers), petrochemical plants (adjustment of syngas ratio, dehydrogenation), and from other streams where hydrogen is present, for example at an ammonia plant. Syngas contains in addition to H<sub>2</sub> and CO impurities like N<sub>2</sub>, CO<sub>2</sub>, CH<sub>4</sub>, and water. It is produced mainly from hydrocarbons by (1) stream reforming and (2) partial oxidation of heavy oils or gasification of coke or coal. There may be a significant variation in the stoichiometric ratio of H<sub>2</sub>/CO for the various chemical syntheses, and the adjustments of syngas ratio may easily be performed by the application of membrane units. The commercial units today are usually either based on polysulfone hollow fibers or spiral-wound CA membranes. Membranes compete with pressure swing adsorption (PSA) and cryogenic systems in hydrogen recovery applications over a wide range of operating conditions. Membrane systems have the advantage of low capital cost and ease of operation. The competing systems however usually deliver the purified hydrogen at almost the same pressure as the feed gas, which results in lower compression costs than those of the membrane system where the hydrogen product always is at a pressure lower than the original feed when using these conventional membranes. Typical performance of membranes for hydrogen recovery in refining applications is shown in Table 4.7 [123].

**TABLE 4.7**  
**Typical Hydrogen Membrane Performance in Refining Applications**

Process Stream	Hydrogen Membrane Recovery			
	Primary Separation	Feed Purity (%)	Permeate Purity (%)	Recovery (%)

**Overview of Fuel Cells: Capacity and Potential Application Areas**

Type of Fuel Cell (FC)	Acronym	Cell Output	Temperature Range (°C)	Field of Application	Special Features
Alkaline FC	AFC	(0.5–5) kW	50–100	Micropower, domestic	Very pure fuel needed
Direct methanol FC	DMFC	Depending on power density	80–100	Domestic, residential	Easily stacked
Proton exchange FC	PEM	(50–250) kW	50–100	Residential, transport	Pure fuel, Pt catalyst
Solid oxide FC	SOFC	100 kW	850–1000	Residential	Large units
Phosphoric acid FC	PAFC	200 kW; 11 MW units	190–210	Power station	1.5% CO tolerance
Melted carbonate FC	MCFC	2 MW; 100 MW units	600–1000	Power station

#### 4.5.1.1 Novel Applications for Hydrogen: Fuel Cells

With the new scenario of hydrogen as a future energy carrier for use in fuel cells, the hydrogen source will no longer only be fossil fuels but will also be produced from biomass and water electrolysis, and possibly from water splitting by algae. There are two ways of producing hydrogen from biomass: either via bio-oil followed by catalytic steam reforming (as for natural gas) or by carefully controlled anaerobic digestion where biogas is produced in mixtures of  $\text{CH}_4$ ,  $\text{CO}_2$ ,  $\text{N}_2$ , and  $\text{H}_2$ . A production based on algae and bacteria is a potentially large resource, but the hydrogen production rate is slow, and large areas are needed. The most appropriate organisms are not yet found, and this resource is still far into the future. Depending on whether the hydrogen is going to be stored, transported, or fed directly to a fuel cell, the specifications for product purity may vary. There is a wide variety of fuel cells under development, some are already commercial and in operation, especially within the transport sector. Table 4.8 presents an overview of the various types of fuel cells, their capacity, and potential applications [124]. A schematic illustration of how two different fuel cells work is shown in Figure 4.24, with pure hydrogen as fuel (left), and with methanol as fuel (right) [124].

When pure hydrogen is to be used as fuel, the gas must first be recovered from the process stream where it is produced. Membranes may be used for this purpose, and several of the new materials under development may be suitable depending on gas volume to be handled and process conditions like temperature and pressure. Along with the introduction of fuel cells, development of small-scale gas-processing units will follow. Several small, integrated production units with direct conversion of fuel to hydrogen gas combined with a membrane unit for hydrogen recovery are patented [125,126].

With reference to Section 4.3 on materials, the proton-conductive palladium (alloys) and carbon membranes will most likely be among the new suitable membranes for hydrogen recovery. Palladium will be a good choice when the highest purity hydrogen is needed, while for this an adsorption unit may be needed in combination with carbon molecular sieves. Both can operate at high temperatures, palladium at the highest. For low temperature applications MMMs have a very promising potential; these materials will be easier to produce on a large scale, and most likely, at a lower price.

**FIGURE 4.24** Schematic illustration of how two different fuel cells work: with pure hydrogen as fuel (left), and with methanol as fuel (right). (From Nunes S.P., *Review on fuel cells*. Presentation at EMS Summer School, NTNU, Trondheim, Norway, 2003. With permission.)

**TABLE 4.9**  
**Market Predictions for Fuel Cell Systems**

Technology Application	Projected Average Annual Shipment	In Europe	In the United States	In Japan	Rest of the World
Distributed generation; low temperature FC	370 MW (starting 2001)	50 MW	100 MW	200 MW	20 MW
Distributed generation; high temperature FC	1,400 MW (starting 2005)	300 MW	500 MW	500 MW	100 MW
Vehicle FC	200,000 engines (starting 2003)	30,000	100,000	60,000	10,000

Source: From Hagler Baily Consultants. EU brochure. In: Nunes S.P., *Review on fuel cells*. Presentation at EMS Summer School, NTNU, Trondheim, Norway, 2003.

The purified hydrogen needs to be stored as liquid (at  $-253^{\circ}\text{C}$ ) or compressed gas at around 200 bar—this is due to the low energy density of hydrogen (0.003 kWh/l at 1 bar and ambient temperature, and 0.5 kWh/l at 200 bar). When used in the transport sector, thick steel cylinders for the compressed gas are needed, and stacks of the cylinders must be carried under or on the top of the vehicle (bus, truck, ferry). For private cars the “direct methanol fuel cell” (DMFC—see Figure 4.24) is more attractive. For a DMFC, methanol ( $\text{CH}_3\text{OH}$ ) is carried as fuel and converted directly to hydrogen.  $\text{CO}_2$  will however then be produced, and depending on the source for the fuel, may add to the emissions of greenhouse gases. Impurities like CO and  $\text{H}_2\text{S}$  in the feed will poison fuel cells.

Another approach to solve the problem of transport of hydrogen over long distances is to introduce hydrogen gas into the existing domestic natural gas net. This is seriously being looked into also by gas suppliers [127]. At the user end, the gas will be decompressed (to  $\sim 7$  bar), and the hydrogen may be separated from the natural gas and fed to fuel cells where applicable. The ratio of  $\text{H}_2$ /natural gas can also be adjusted by membranes to specified mixtures of natural gas and hydrogen (Hythan; a mixture of hydrogen and methane), mixtures which are currently being tested out as an alternative fuel in the transport sector to reduce emissions while waiting for the fuel cells. The percentage of hydrogen mixed into the transport pipe system must be carefully evaluated for safety reasons, leakage, and material fatigue of the steel pipes. The preferred solution for production of  $\text{H}_2$  in future would be to use renewable energy (solar, wind, waves) for electrolysis of water, or direct production by algae.

The market predictions for fuel cell systems worldwide presented by Hagler Bailey is shown in Table 4.9 [128].

## 4.5.2 $\text{CO}_2$ REMOVAL

Separation of  $\text{CO}_2$  from gas streams is required in four areas: (1) purification of natural gas (gas sweetening), (2) separation of  $\text{CO}_2$  from enhanced oil recovery (EOR) gas streams, (3) removal of  $\text{CO}_2$  from flue gas, and (4) removal of  $\text{CO}_2$  from biogas. A fifth area vital for the space age should be mentioned: removal of  $\text{CO}_2$  from life support systems onboard space ships, and also in submarines. All these applications have different specifications for the purified gas or for the recovered  $\text{CO}_2$ , and future membrane applications will most likely be based on tailor-made materials.

### 4.5.2.1 $\text{CO}_2$ Removal from Natural Gas

The application of membranes today for  $\text{CO}_2$  recovery and natural gas processing is mainly used for moderate-volume gas streams. For large-volume gas streams, membrane separation today cannot yet compete with the standard amine absorption—the flux and selectivity of the membranes are too low for processing large gas volumes. The membrane separation units found at sites today will often be hybrid solutions with membranes combined with traditional technology. The  $\text{CO}_2$  (and  $\text{H}_2\text{S}$ ) must be removed from crude natural gas in order to increase heating value and reduce corrosion during transport and distribution. The amount of  $\text{CO}_2$  in natural gas is typically in the range of 10% by volume or less, and the gas is at very high operating pressures (35–80 bar or even higher). The specifications for removal of sour gases are very strict, and content of  $\text{CO}_2$  should typically be brought down to  $< 2$  vol% for sales gas. The membranes in operation are typically made from polyimides (PI) as hollow fibers, or asymmetric cellulose acetates (CA) as spiral wound modules. The PI membranes have a higher flux and selectivity ( $\sim 20$ ) compared to the CA membranes, and are basically hydrophobic and therefore less vulnerable to water. The CA are, however, more resistant to heavier hydrocarbons. The hollow fiber configurations will be able to handle large gas volumes with relatively few modules due to high packing density ( $\text{m}^2/\text{m}^3$ ).

Recovery of  $\text{CO}_2$  in the oil and gas production is of major importance to promote enhanced oil recovery (EOR) from depleted fields: High pressure  $\text{CO}_2$  is then pumped back into the reservoir at the periphery of the field and diffuses through the formation to drive residual oil toward the wells. The recycled gas generally needs to have a purity of at least 95 vol%  $\text{CO}_2$ .

The main companies producing membranes for  $\text{CO}_2$  removal are listed in Table 4.6.

**FIGURE 4.25** Picture from Qadirpur, Pakistan, the world's largest membrane-based natural gas processing plant. (From Dortmund D., Doshi K., Recent developments in CO<sub>2</sub> removal membrane technology [http://www.uop.com/gasprocessing/TechPapers/CO<sub>2</sub>RemovalMembrane.pdf](http://www.uop.com/gasprocessing/TechPapers/CO2RemovalMembrane.pdf) (accessed March 2004). With permission.)

Some examples of installed membrane units for gas processing are given below:

#### EXAMPLE 1

One of the earliest (and largest) membrane plants for EOR was at the SACROC unit in West Texas, which started up in 1984. (The hollow fiber membrane units are owned and operated by Cynara, a subsidiary of Dow.) In this process, the purified CO<sub>2</sub> stream from the membranes is further treated with hot potassium carbonate before reinjection into the oil field. A single-membrane stage is used followed by multiple banks of membrane permeators in parallel, thus plant performance can be optimized under varying feed conditions by adjusting the number of permeators in operation. (Over the years the CO<sub>2</sub> content increased from 0.5 vol% up to a level of ~60 vol%.) The Cynara membrane system would successfully process 70 million SCFD of gas containing 40–70 vol% CO<sub>2</sub> around 1990 [122].

#### EXAMPLE 2

In Qadirpur, Pakistan, the world's largest membrane-based natural gas processing plant is situated (see picture in Figure 4.25). The plant is processing 265 MMSCFD natural gas at 59 bar, and with plans for expanding the plant to handle 400 MMSCFD [129]. The CO<sub>2</sub> content is reduced from 6.5 mol% to less than 2 mol% using a CA membrane. The plant is also designed for gas dehydration with membranes.

#### EXAMPLE 3

Other operating membrane plants around the world include (1) Kadanwari, Pakistan, where a two-stage unit for treatment of 210 MMSCFD gas at 90 bar is operating, (2) Mexico, where an EOR facility is installed to process 120 MMSCFD of gas containing 70 mol% CO<sub>2</sub>, and (3) Egypt, where a three stage unit is operating at Slalm & Tarek with each unit treating 100 MMSCFD natural gas at 65 bar.

All the plants mentioned are operating with membranes based on hollow fiber polyimides or spiral-wound CA, which is considered proven technology. The environmental aspect related to CO<sub>2</sub> as a green house gas has triggered the development of better membranes for CO<sub>2</sub> removal—this is more closely discussed in Section 5.2.3.

#### 4.5.2.2 CO<sub>2</sub> Removal from Biogas

Biogas will have different compositions depending on the source where it is being produced (see Table 4.10) [130]. If the methane is going to be used for high energy fuel, it must be purified to contain ~95 vol% CH<sub>4</sub>. Processing of biogas may, in some cases, be handled by using the existing CO<sub>2</sub>-selective membranes. However, the presence of nitrogen in biogas is a major challenge, especially when the biogas is produced from a landfill (see Table 4.10). Nitrogen will remain on the feed side with

**TABLE 4.10**  
**Composition of Biogas from Different Sources**

Component	Municipal Wastewater Treatment Plants (vol%)	Dedicated Reactors (Organic Waste) (vol%)	Landfills (vol%)
CH <sub>4</sub>	55–75	50–90	40–55
CO <sub>2</sub>	25–45	10–50	30–40
N <sub>2</sub>	Traces	Traces	2–25
O <sub>2</sub>	Traces	Traces	0–5
H <sub>2</sub>	<1	<1	<1
H <sub>2</sub> S	<1	<1	<1
H <sub>2</sub> O	4–7	4–7	4–7

Source: From Maltesson, H.Å., *Biogas för fordonsdrift*. KFB, Stockholm, 1997 (in Swedish).

the methane, and fuel specifications may be difficult to reach. About 3200 m<sup>3</sup> (STP)/h of biogas can be collected from a medium-size dumpsite, which is equivalent to 1700 L/h of fuel oil [131]. The standard way of utilizing the biogas (if at all considered) is by burning the gas on site in combination with a turbine, thus producing energy. This may be sensible if the energy distribution net is easily available. A more environmental friendly solution is to upgrade the gas to fuel specifications by using membranes. Several pilot plants are in operation both in the United States and in Europe based on existing membrane materials. New CO<sub>2</sub>-selective materials will most likely enhance the development of utilizing this valuable energy resource (see Section 4.5.2.3).

#### 4.5.2.3 Novel Applications for CO<sub>2</sub> Capture

Due to the environmental focus on CO<sub>2</sub> emissions around the world, there are numerous CO<sub>2</sub> selective materials under development—several hundred polymers are reported (articles and patents). The main challenge for bringing these membranes into commercialization is to document durability over time (maintaining separation properties) during real operating conditions.

##### 4.5.2.3.1 Natural Gas Sweetening

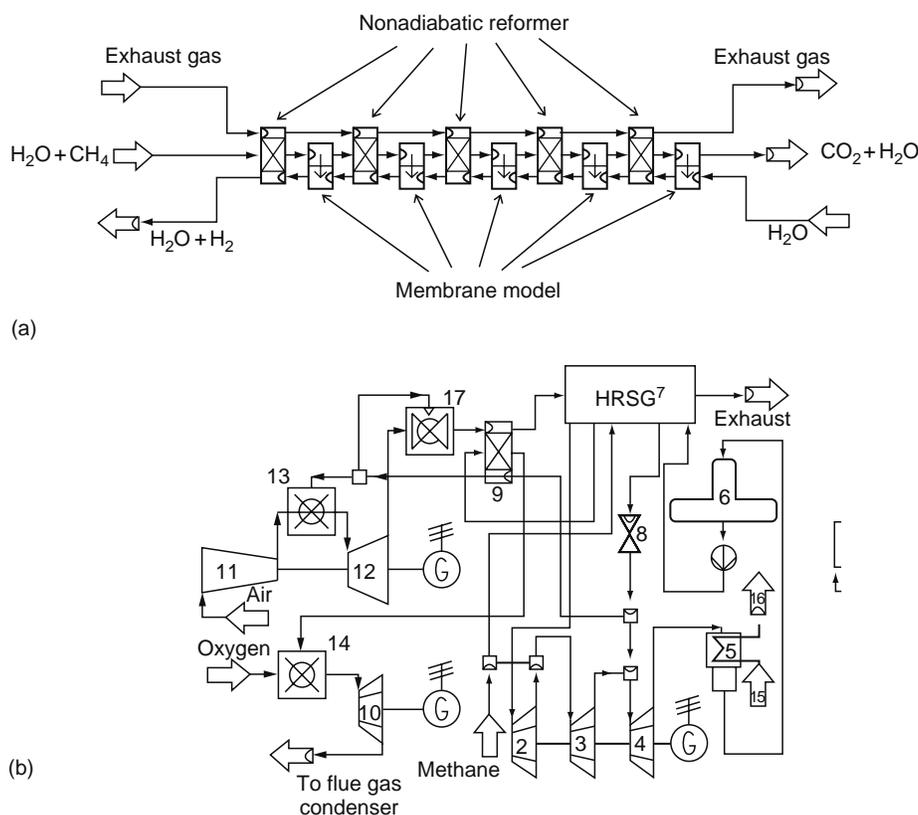

New materials for natural gas sweetening are basically based on further developments of existing polymeric materials, which can easily be made into hollow fiber or spiral-wound membrane modules. This is mainly due to the large permeation areas needed. When CO<sub>2</sub> permeates the higher hydrocarbons, C<sub>3+</sub> will co-permeate. It is important that the sales gas specifications can be met when membranes are being used for CO<sub>2</sub> removal and dew point control. Several promising materials are under development and being tested out—the market potential is huge. This development is typically done in cooperation with the oil and gas companies, and little information is being released until the membrane is ready for commercialization. MMMs with high selectivities in favor of CO<sub>2</sub> will still need many years of development to compete with tailor-made polymeric membranes as well for this application. The cardopolymers as well as the facilitated transport polymers may be interesting candidates for natural gas sweetening.

##### 4.5.2.3.2 CO<sub>2</sub> Removal from Flue Gas

Removal of CO<sub>2</sub> from exhaust gas from combustion is a major driver for membrane material development. Also integrated membrane solutions to power cycles (gas turbines) are in focus. In the exhaust gas, CO<sub>2</sub> will be in a mixture with H<sub>2</sub>O, N<sub>2</sub>, NO<sub>x</sub>, O<sub>2</sub>, possibly SO<sub>2</sub>, and some hydrocarbons, and at low pressure and high temperature. In addition, there will also be dust particles in the gas. The membrane separation will, in this case, meet challenges, which are different from those for natural gas sweetening. Integrated membrane solutions are often being considered when combustion/energy production is discussed, both in precombustion and in postcombustion. A solution with integration of H<sub>2</sub>-separating membrane technology in gas turbine processes for CO<sub>2</sub> capture is shown in Figure 4.26 [132].

Membranes do not tolerate particles, so the gas has to be filtered before separation. Then for several membrane materials water vapor may also be a problem, causing plugging (inorganic microporous materials) or swelling (polymeric materials). Hence for these applications, the gas must be dried. Depending on the specifications for the CO<sub>2</sub>, co-permeation of gases (especially remaining HC) may be a problem. What can then be recommended for removal of CO<sub>2</sub> from flue gas? Some alternatives are presented below:

- Securing complete combustion using oxygen-enriched air (will give higher CO<sub>2</sub>% in exhaust gas, hence higher driving force for CO<sub>2</sub> removal)
- Using an integrated solution with a gas turbine so that CO<sub>2</sub> gas is removed at higher pressure (securing higher driving force over the membrane)

**FIGURE 4.26** A suggested integration of  $H_2$ -separating membrane technology in the gas turbine process for  $CO_2$  capture. (a) Shows a membrane steam reactor model with  $H_2$  separation; this corresponds to unit 9 in (b) showing the flowsheet of a combined cycle with the membrane reactor integrated. (From Jordal K., Bredesen R., Kvamsdal H.M., Bolland O., *Energy*, 29, 1269, 2004. With permission.)

- High temperature in the flue gas ( $>100^\circ C$ ) most likely requires inorganic materials; hence ceramics or carbon membranes could be chosen (see Section 4.3.4)
- If the gas is cooled down, a  $CO_2$ -selective polymeric membrane may be used (cardopolymers and carrier membranes are especially interesting. Problem: compression of exhaust gas may be needed; see Section 4.3.1)
- If the gas is cooled, a  $CO_2$ -selective membrane with facilitated (carrier) transport may be used with vacuum or water vapour sweep on permeate side (no compression needed, only a fan; see Section 4.3.1.2)
- For large gas stream volumes the membrane contactor using amines as absorbent may be the best solution (see Section 4.4.4 and below)

The membrane contactor for  $CO_2$  removal deserves special attention. It can be used for natural gas treatment, dehydration, and removal of  $CO_2$  from flue gas (see Section 4.4.4). A contactor (see Figure 4.22) patented and developed for this purpose by Aker Kvaerner—pilots have been installed and tested both in Norway (at Kårstø) and at a gas terminal in Scotland. This module is based on PTFE membranes. A different commercial contactor based on polyimide membranes was recently installed at Santos Gas Plant in Queensland, Australia (December 2003). Santos is the largest gas producer in Australia.

#### 4.5.2.3.3 $CO_2$ Removal from Biogas

Biogas is a valuable energy resource, which can be processed in small plants all over the world. Biogas has different compositions depending on the source. The gas is easily collected from dumpsites or anaerobic digesters, and may be processed at moderate pressures and ambient temperature. Membrane systems are excellent for this purpose, operating at pressures in the range of 5–7 bar. The choice of membrane materials are therefore also quite flexible, and small-scale processing units are likely to be developed—a few already exist. Highly  $CO_2$ -selective polymeric membranes (cardopolymers, fixed-site carriers), carbon molecular sieves, mixed matrix, or biomimetic materials are potential membrane materials for this application. The purified methane can then be compressed to 300 bar, and stored in tanks for fuel in the transport sector, or for conversion to methanol used for fuel cells.

#### 4.5.2.3.4 CO<sub>2</sub> Removal in Life Support Systems

CO<sub>2</sub> removal in life support systems is becoming increasingly important as man is going into space for longer journeys. The standard way of removing CO<sub>2</sub> from breathing air is to adsorb the gas on molecular sieves, mainly using carbonates. This is a safe way as long as there is enough adsorbent. The preferred way would be to separate CO<sub>2</sub> from the air without using adsorbents but rather highly CO<sub>2</sub>-selective membranes, then dispose of it or bring it back into the life cycle by using water (from urine) and green plants grown artificially in space. Nanostructured materials, fixed-site carriers, or biomimetic membranes would most likely be suitable for this application.

### 4.5.3 AIR SEPARATION

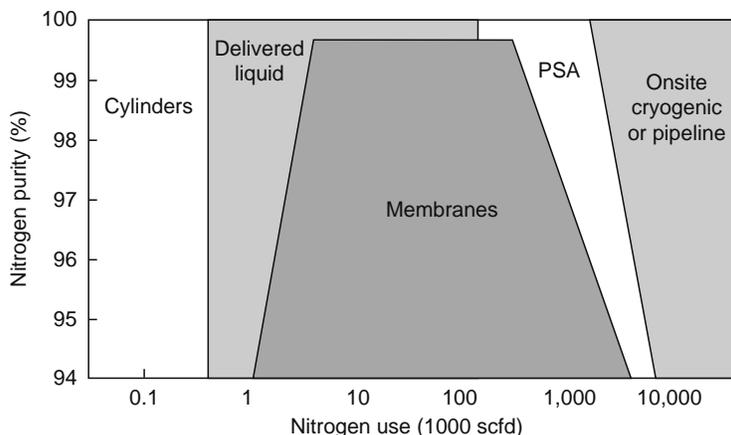

Membranes for air separation have become increasingly important over the years, and the development of continuously better materials has been rapid since Dow and Permea presented their first membrane systems in 1985. The first membranes used for air separation were based on poly(4-methyl-1-pentene) (TPX) and ethyl cellulose and had selectivities for O<sub>2</sub>/N<sub>2</sub> around 4–5 [133]. Today second generation air separation membranes are on the market, usually as hollow fiber modules with very high packing density, and based on polymers such as polysulfones (PS) and poly(phenylene)oxide (PPO). Remembering the very strong inverse relationship between selectivity and permeability for oxygen and nitrogen as illustrated by Robeson in Figure 4.1 [4], it may easily be understood that there is a major difference in producing high-purity nitrogen compared to high-purity oxygen. Air separation using membranes is today considered proven technology, and there are several producers in addition to Dow (now upgraded system Generon II) and Permea (Prism Alpha; now Air Products)—see Table 4.8. Detailed information on membrane solutions for air separation are found in many textbooks, handbooks, and references [1,50,122,133].

#### 4.5.3.1 Production of High-Purity Nitrogen

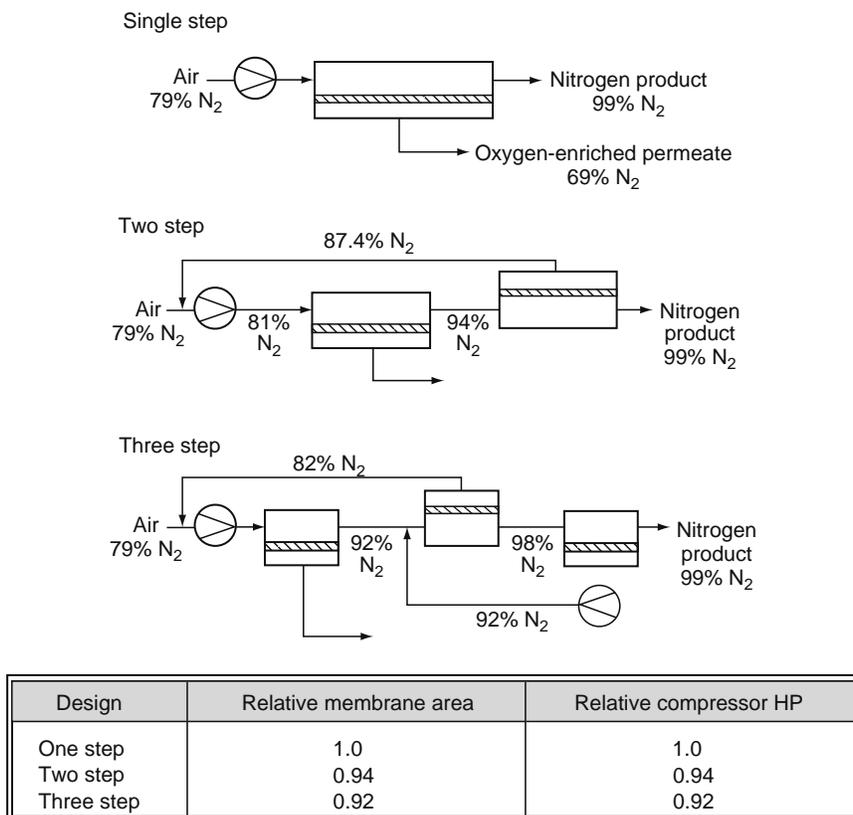

High-purity nitrogen is used for many applications as blanketing gas in oil and gas industry, as purge and blanketing in chemical industry, in food industry for packaging, and various others. When air is separated by polymeric membranes, oxygen will be the faster permeating component with a selectivity in the range of 2–9 compared to nitrogen. (With carbon membranes selectivity ~15 has been measured.) This means that when compressed air is fed to the membrane, nitrogen is retained at high pressure on the feed side, which is usually an advantage. The competing separation technologies are typically cryogenic distillation and PSA. Figure 4.27 illustrates the recommended production range for applying the different technologies [133]. Even with low selectivity membranes, high-purity nitrogen may be obtained (99.9%), but the cost of the system increases significantly in the range of 95%–99% nitrogen purity. Various process designs may be considered for cost reduction. Figure 4.28 illustrates how a process may be optimized to reduce membrane area and compressor cost for a required product of 99% purity nitrogen. The three-step process will however be limited to large systems where energy and membrane area savings compensate for the extra complexity and higher maintenance cost of a second compressor. A comprehensive discussion of factors affecting the design of nitrogen plants is given by Prasad et al. [134].

#### 4.5.3.2 Oxygen-Enriched Air

Oxygen-enriched air will be produced on the low pressure permeate side of the air-separating membranes. The oxygen-enriched permeate stream is usually vented, but there is an increasing interest in using this gas for combustion. High-purity oxygen

**FIGURE 4.27** Illustration of the approximate competitive range of current membrane nitrogen production systems. Many site-specific factors can affect the actual system selection. (From Baker R., *Membrane Technology and Applications*, McGraw-Hill, New York, 2000. With permission.)

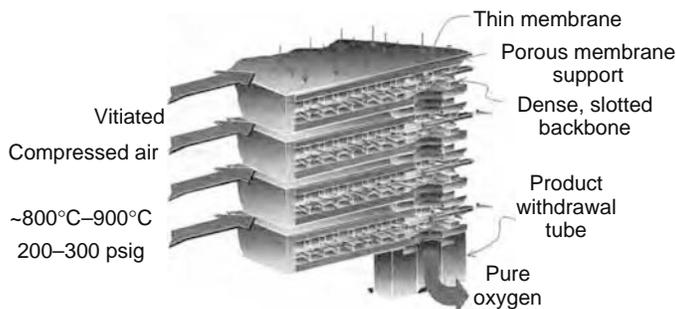

**FIGURE 4.28** Illustrations of single-step, two-step, and three-step designs for nitrogen production from air. The table shows the effect of the different designs on membrane area and energy demand for compressor. (From Baker R., *Membrane Technology and Applications*, McGraw-Hill, New York, 2000. With permission.)

cannot be produced with the polymeric air separation membranes. Calculations will easily show that with a selectivity of 8 for O<sub>2</sub>/N<sub>2</sub>, and with an infinite pressure ratio and zero stage cut, the permeate can only reach as “best case” 68% purity for O<sub>2</sub>. These constraints explain why oxygen-enriched air in these systems usually is in the range of 30%–50% purity for O<sub>2</sub>.

### 4.5.3.3 Novel Developments for High-Purity Oxygen

In Section 4.3.5.3 it was stated that oxygen-conductive membranes are under development. These membranes are suitable for advanced power generation requiring oxygen for combustion or gasification, and are based on zirconia and perovskite where oxygen is transported through the material as O<sub>2</sub><sup>-</sup>. The materials are stable at very high temperatures (>500°C). A schematic illustration of the ion transport membrane (ITM) developed by Air Products is shown in Figure 4.29 [13]. Details on this

**FIGURE 4.29** A schematic illustration of the ion transport membrane (ITM) device developed and patented by Air Products and Chemicals, Inc. The supported membrane wafers are separated by spacer rings and attached to a common product withdrawal tube. (From Armstrong P.A., Stein V.E.E., Bennet D.I., Foster E.P., *Ceramic Membrane Development for Oxygen Supply to Gasification Applications*, Air Products and Chemicals, Inc., Allentown, PA, 2002. With permission.)

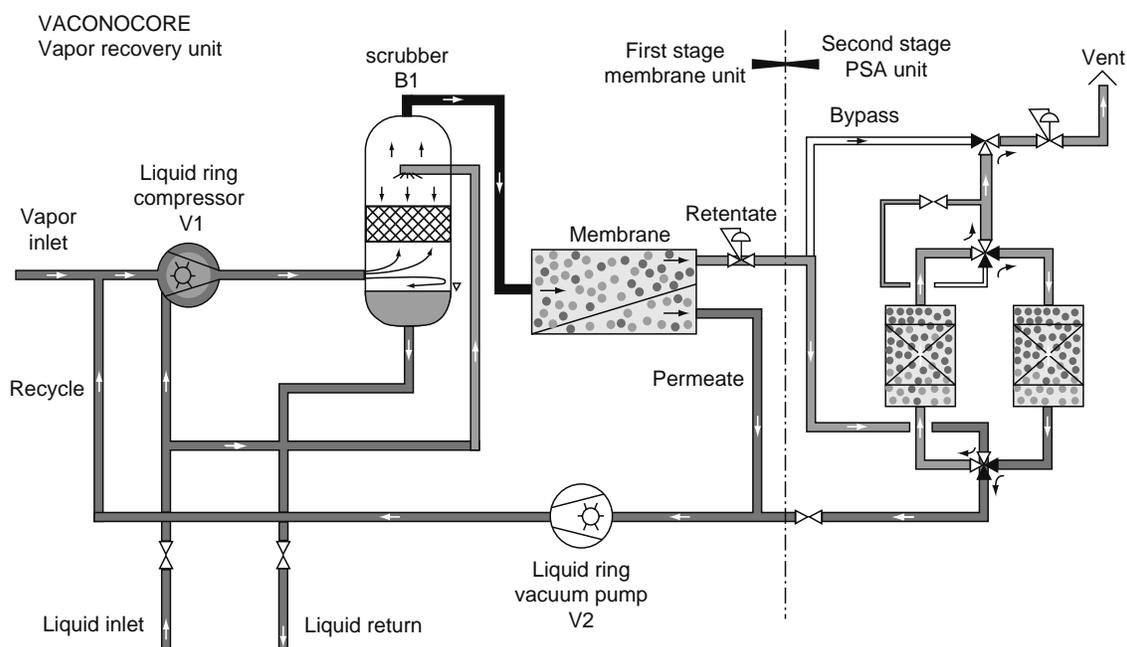

technology can be found in Ref. [135]. The Danish company, Haldor Topsoe A/S, has presented a patented solution with an integrated ion-conducting membrane for autothermal steam reforming [136]—several other patents are being announced.

#### 4.5.4 RECOVERY OF VOLATILE ORGANIC COMPOUNDS

With the increased focus on climate changes and greenhouse gases, the need for reducing VOC emissions has been brought into focus. Major sources for these emissions are evaporation from oil and gas tankers during transport and bulk handling of oil at buoys and terminals, refineries, and petrochemical plants. On the basis of international agreements on Long Range Transboundary Air Pollution (Geneva convention of 1979 with later protocols) and Clean Air Act Amendments of 1990 in the United States, various technologies for VOC recovery have been developed. The main technologies are based on recirculation of the VOC rich stream for absorption in the oil. For large gas volumes this demands a complicated system of cooling and recompressions of the VOC and venting of the purified air. Process units for installation on tankers are developed by several companies (Aker Kvaerner Process Systems, Hamworthy and others). For moderate volume air streams, membrane solutions exist. The GKSS module (see Figure 4.20) was developed for this purpose, and is today considered proven technology. A rubbery membrane allowing the VOCs to permeate and inerts to be retained is used. A hybrid solution with PSA may be necessary to remove the traces of VOC before the gas is vented (see Figure 4.30 [137]). The challenge is still to develop efficient process schemes for filling and unloading of tankers. The volume percent VOC in the inert gas stream may vary between 8% and 60% from start to end of filling operation—this complicates the recovery process. Combinations with membranes for concentrating the VOC before absorption are being looked into.

#### 4.5.5 SEPARATION OF HYDROCARBONS—NOVEL MEMBRANE DEVELOPMENTS

Successful separation of alkanes and alkenes has been documented when microporous membranes have been used [79,138]. The physiochemical properties, size, and shape of the molecules will play an important role for the separation, hence critical temperatures and gas molecule configurations should be carefully evaluated for the gases in mixture. On the basis of gas properties and process conditions, the separation may be performed according to selective surface flow or molecular sieving (refer to Section 4.2 on transport). The transport may also be enhanced by having a Ag compound in the membrane. The  $\text{Ag}^+$  ion will form a reversible complex with the alkene, and facilitated transport results. Selectivities in the range of 200–300 have been reported for separation of ethene–ethane and propene–propane [138]. Successful separation of alkanes and alkenes will be important for the petrochemical industry. Today the surplus hydrocarbons in the purge gas are usually flared. Membranes which should be suitable for this application are the carbon molecular sieves (see Section 4.3.2) and nanostructured materials (Section 4.3.3).

**FIGURE 4.30** Illustration of a hybrid solution for removal of organic vapor from a gas stream, as documented by Vaconocore. (From Ohlrogge K., Wind J., Behling R.D., *Erdoel & Kohle Erdgas Petrochemie*, 46, 326, 1993. With permission.)

## 4.5.6 OTHER APPLICATIONS

### 4.5.6.1 Water Vapor Removal from Air

Membranes are used to dehydrate process air streams as replacement for desiccant dryers or adsorption systems. Such membrane units have been on the market for many years, but they are mainly for small gas streams. The membranes being used have very high water to air selectivity. The dehumidification units are usually connected to a compressed air line, and loss of pressurized air through the membrane may be a major cost.

### 4.5.6.2 Dehydration of Natural Gas

Natural gas has to be dried in order to prevent water from freezing or hydrates to form in pipelines for gas distribution. The potential application of membranes for gas dehydration is very large. There are already numerous polymers available with very high selectivities for water vapor: 500–2000 are beneficial, and a breakthrough for commercialization of a few materials is to be expected. The water permeance should preferably be at least  $30 \text{ m}^3 \text{ (STP)/m}^2 \text{ h bar}$  [139]. The problem is that with increasing selectivity at a given water vapor flux, the necessary permeation area also increases. If the gas on the permeate side could be used for low-pressure fuel at the site, a membrane solution for dehydration would be economical and competitive to glycol dehydration. If the permeate gas has to be recompressed, the costs will probably be too high. Permea Maritime Protection (division of Air Products) is one of the companies having presented a commercial unit, already installed in the North Sea.

Zeolites have been used for many years as an adsorbent in a wide range of industrial applications (also for smaller volumes of natural gas) because of the regular and controllable pore size in their crystalline structure. The highly hydrophilic nature of these materials means that water is always preferentially adsorbed. Regeneration is however necessary when the adsorbent is fully loaded.

### 4.5.6.3 Helium Recovery

Helium is present in low concentrations in natural gas, and is also used as a diluent in breathing gas mixtures for deep-sea divers. Helium is a valuable gas, and is therefore important to recover. As the permeability of helium normally is slightly higher than hydrogen, the recovery of helium from natural gas may be feasible with hydrogen separation membranes. However, when the concentration is very low, a very high selectivity for  $\text{He}/\text{CH}_4$  is needed ( $>500$ ) or a staged system with recompression. For recovery of helium from breathing gas, a selectivity of  $\text{He}/\text{N}_2$  should be in the range 50–100 [140].

### 4.5.6.4 Recovery of Aggressive Gases: $\text{Cl}_2$ and $\text{HCl}$

Membranes for purification or recovery of aggressive gases have been under development for many years, and is expected to be commercialized within a few years. The main challenge for membrane separation of gases like  $\text{Cl}_2$  and  $\text{HCl}$  is the durability of the material—this has been thoroughly documented by several researchers [31,60,141,142]. The only polymers that can withstand the aggressive process environment are the perfluorinated materials. These membranes do not yet have satisfactory separation properties for  $\text{Cl}_2$  or  $\text{HCl}$  in mixtures with more inert gases. There are two ways for membrane development for this application: (1) using perfluorinated compounds to surface modify microporous glass membranes or (2) possibly make a mixed matrix membrane with the perfluorinated polymer as the continuous phase and molecular sieving glass fibers as the sieving phase. The potential for membrane application within this field is very large as chlorine is a widely used chemical in numerous industries worldwide. The competing purification methods today are based on chemical reaction with additives or cryogenic distillation.

## 4.6 SUMMARY

It can be concluded that there is a potential for membrane separation of almost any gas from a mixture of gases if physical and chemical properties are carefully considered as well as material properties and durability, possible transport mechanisms, and optimum process conditions evaluated. Creative reflection and advanced research will be able to develop this environmental friendly separation technique for applications within many areas in the future, and hopefully be able to displace old, energy-consuming (and not so clean) technology or combine with them in hybrid process solutions. The costs of the final solution will always be a major issue for commercialization.

## ACKNOWLEDGMENTS

The author wants to thank colleagues and researchers in the membrane research group, MEMFO at NTNU, for valuable discussions and patience while writing up this chapter. Special thanks to the following members of my research group: Jon Arvid Lie, Arne Lindbrathen, and Taek-Joong Kim for valuable help with references and figures.

## 5.1 INTRODUCTION

The contributions of separation to human society cannot be underestimated. Different types of chemicals meet various requirements in our daily life. Most of these are synthetics manufactured by different techniques. These chemicals are an essential part of our life and it is impossible to imagine a civilized society devoid of them. These chemicals range from foods, medicinal drugs, and colorful dyes of our clothes to detergents for washing and cleaning of every essential commodity. There is very little doubt that much of these activities involved in the manufacture of the synthetics are causing certain damage to the delicate balance in the ecosystem. Developments in “Green” technologies are not just academic curiosities but are increasingly finding commercial applications. The widespread use of the natural resources has led to depletion of natural, nonrenewable energy sources. There is an ever-increasing awareness about optimum utilization of the nonrenewable sources (NRS). One major mode of consumption of NRS in the chemical process industries (CPI) is the use of fossil fuels as a source of

heating the various process equipments. Separation processes are an integral part of the CPI. Amongst the various separation processes used in the CPI, the major consumption of fuels in the CPI occurs in distillation. It is impossible to build a chemical plant without using distillation at some point in the process. Even isolation of natural products such as essential oils, spices, photochemical, etc. cannot be accomplished without resorting to distillation. Distillation as commonly employed uses a high grade heat in the reboiler and rejects the same as very low-grade heat in the condenser. With the awareness about optimum and efficient utilization of these NR fuels, the CPI is looking at alternatives to this highly energy intensive operation. Thus, membrane separations that either do not involve a phase change or use low-grade heat for the phase change during separation are becoming significantly important as an alternative to distillation. Several new, promising approaches have been made recently. A large number of separation processes are available for separation of components from a mixture. Amongst these the membrane-based separation techniques include microfiltration, ultrafiltration, nanofiltration, reverse osmosis, and pervaporation (PV). Pervaporation in which permeation through a dense membrane is followed by evaporation is the subject of this chapter.

Kobar first used the term “Pervaporation” in 1917 [1] to denote a phenomenon observed during laboratory experiment. In the course of some experiments on dialysis, his assistant, C.W. Eberlein, pointed out the fact that a liquid in a collodion bag, which was suspended in air, evaporated, although the bag was tightly closed. These investigators alluded it to evaporation, presuming that it has taken place through a small aperture at the top of the bag. Further experiments and especially the speed of evaporation soon led them to the conclusion that aqueous vapor is given off through the membrane. This phenomenon was termed pervaporation by Kobar in an article published in the *Journal of American Chemical Society* in 1917 [1].

In 1952, Schwob [2] in his doctoral thesis employed the PV process for dehydration of alcohol using a regenerated cellulose film. Between 1958 and 1962, Binning et al. [3] carried out a series of investigations using hydrophobic membranes such as polyethylene for the separation of hydrocarbon mixtures. Meanwhile, Neel and coworkers had also started systematic PV studies [4–6]. In between, Tusel and his coworkers also started to work on dehydration through PV [7]. Besides these, investigations by Sander [8] and Asada [9] on pervaporative dehydration resulted in establishing PV as a safe and energy efficient process for the separation of components in a homogeneous liquid mixture.

PV as a separation process has potential applications in almost all categories. These include: (i) industrial dehydration applications, such as alcohol–water, organic–water, and chlorinated-hydrocarbon water system [10–15]; (ii) removal of organics from water [16–20]; and (iii) separation of organic–organic mixtures [21–27]. Although the first application category has seen widespread application, the other two are not as commercially successful as the first category. The process is currently best identified with dehydration of ethanol, isopropyl alcohol, and ethylene glycol. Due to its favorable economics, efficiency, and simplicity, PV can be easily integrated with distillation and other rectification processes. In the mid 1970s, the German company GFT first commercialized an economical process for dehydrating ethanol producing anhydrous ethanol at high purities that rival azeotropic distillation. Subsequently, continuing into the early 1980s other integrated distillation/PV plants were built in Europe and Asia. Currently, a number of commercial PV plants exist for recovery of solvents, removal of organics from wastewaters, dealcoholization of wines and liquors, as well as many more for ethanol dehydration. A 150,000 L/day ethanol dehydration plant in Betheniville, France was started up in early 1988 and became the world’s largest PV facility. The groups of Mulder, Rautenbach, Huang, Cabasso, and Pangarkar have also carried out considerable work at various universities.

Pervaporation has the following advantages:

1. Very low capital and operating cost: The separation could be made more economical by using a hybrid membrane process, i.e., a combination of distillation and pervaporation processes. Thus, a part of the total separation employs distillation where it is economical. PV replaces the subsequent separation where distillation becomes expensive. The overall operating cost of such a hybrid process is much lower than that of distillation alone.
2. Azeotropes can be readily broken by using an appropriate membrane.
3. No additive is needed for the final separation.
4. Easy operation and space saving.
5. Reduced energy demand, low-grade heat, and a vacuum pump are required.
6. Freedom from environmental pollution caused by the entrainers.
7. Possibility of multipurpose application and easy scale-up.
8. Membrane properties can be varied and adjusted to suit different applications.
9. Closed loop operations with only a small volume of recycled permeate.

Selective separation of liquids by pervaporation is a result of selective sorption and diffusion of a component through the membrane. PV process differs from other membrane processes in the fact that there is a phase change of the permeating molecules on the downstream face of the membrane. PV mechanism can be described by the solution–diffusion mechanism proposed by Binning et al. [3]. According to this model, selective sorption of the component of a liquid mixture takes place at the upstream face of the membrane followed by diffusion through the membrane and desorption on the permeate side.

Based on the above proposed mechanism pervaporation can be divided into three distinct steps:

1. Sorption: At the membrane–liquid interface, the membrane sorbs the components according to their relative sorption behavior.
2. Diffusion: The sorbed components diffuse across the swollen membrane under a chemical potential gradient.
3. Evaporation: Permeate desorption takes place at the downstream surface of the film.

Selectivity and productivity depend on sorption and diffusion. Sorption is dictated by thermodynamic properties, namely, the solubility parameter of the solute(s)/membrane material system. On the other hand, the size, shape, molecular weight of the solute, and the availability of inter/intra molecular free space of the polymer largely govern the second property, the diffusion coefficient. For an ideal membrane, both the sorption and diffusion processes should favor the chosen solute. If one step becomes unfavorable for a given solute the overall selectivity will be poor [28].

Desorption on the downstream side of the membrane is generally considered to be rapid and nonselective. The gas phase diffusivities in the final step of transport are very high and hence this step offers the least resistance in the overall transport process. As a separation process, pervaporation relies on the difference in membrane permeabilities, which are dependent on the thermodynamics activities of the components to be separated.

This chapter deals with the following:

1. Basic aspects of PV and the related theory with a view to familiarize the reader with the selection of the membrane material for a given application.
2. The membrane modules used industrially and their specific areas of applications.
3. A comprehensive survey of the literature on PV for all the three categories is finally presented to update the reader with the latest research findings.

## 5.2 TRANSPORT THROUGH MEMBRANES

The mode of transport through a membrane may be passive, active, or facilitated type. In passive transport, the membrane acts as a barrier and permeation of the components is determined by their diffusivity and concentration in the membrane or just by their size. In facilitated transport along with the chemical potential gradient, the mass transport is coupled to specific carrier components in the membrane. In active transport driving force for transport is achieved by a chemical reaction in the membrane phase.

### 5.2.1 TRANSPORT IN PERVAPORATION

In PV, the transport of the solutes occurs under a chemical potential gradient. This gradient is maintained by applying a lower pressure at the downstream face of the membrane in the classical PV mode. The low pressure creates a lower activity at the downstream face as compared to the higher activity at the feed face where the solutes are in liquid phase. A different method, which can also maintain an activity gradient, utilizes an inert carrier gas as a sweep gas past the downstream face of the membrane. The inert gas plays the same role as vacuum in creating a driving force for transport through the membrane. The whole transport process is purely physical since no chemical reaction with either a carrier or membrane material occurs. The permeate is passed through a condenser wherein the solutes are condensed. When a sweep gas is used to create the driving force, the presence of noncondensable components calls for much lower temperatures due to the much lower dew point of the mixture. This fact must be considered while designing the condenser and coolant circuit as well calculating the operating cost. Overall the vacuum mode is more popular since no extra cost associated with the sweep gas and its recirculation is involved. Different models have described passive transport through the membrane in PV. Mulder [29] has discussed this subject in detail. The following discussion is therefore limited to the two main models:

#### 5.2.1.1 Preferential Sorption–Capillary Flow Model

The preferential sorption–capillary flow model, proposed by Sourirajan and Shiyao [30], depicts the membrane as a porous barrier. The model is based on a combination of preferential sorption of the rapidly permeating solute followed by flow through the capillaries and finally evaporation at the downstream face of the membrane. The extent of separation is governed by the effective molecular sizes of the permeants, the pore size, and its distribution besides the interactions between the membrane polymer and the solutes, which result in preferential sorption. According to the PSCF model liquid feed flow through the cylindrical pores of the membranes is rate determining. Liquid–vapor transition occurs at the pore outlet in the downstream side and phase equilibrium between liquid–vapor is established. A straight cylindrical pore is assumed at the surface layer of the membrane and cylindrical coordinates ( $r, z$ ) are set in the pore. Diffusion forces working on components A and B (permeants),

the viscous force, and the pressure force are those which have to be balanced at the steady state of the liquid movement in the pore leading to the equation:

$$\frac{D^2U}{dr^2} + \frac{1}{r} \frac{dU}{dr} + \frac{1}{\eta} \frac{(p_2 - p_3)}{\delta p} = 0 \quad (5.1)$$

where

$U$  is the solution velocity

$\eta$  is the solution viscosity in the pore

$\delta$  is the length of the pore

$p_2$  and  $p_3$  are effective pressure (atmospheric pressure/RO pressure) at pore inlet and outlet A and B

To find the concentration of A in the permeate, diffusive force is considered to work only on A, friction force between A and B, and A and pore wall. This leads to the differential equation:

$$-RT \frac{d \ln a_A(r,z)}{dr} / r = r, \quad -(c_{AB} + c_{AM})U(r) \frac{C_{A3}(r)}{C_A(r,z)} + \chi_{AB}U(r) \frac{C_{B3}(r)}{C_B(r,z)} = 0 \quad (5.2)$$

where

$a$  is the activity

$\chi_{AB}$  is the friction constant between A and B

$\chi_{AM}$  is the friction constant between component A and pore well

$C_{i3}(r,o)$  is the molar concentration at the pore outlet, where  $i$  represents solute A or B

$C_i(r,z)$  is the molar concentration in the pore at a position represented by a cylindrical coordinate  $r, z$ , respectively, where  $i$  represents solute A or B

Both Equations 5.1 and 5.2 can be solved with appropriate boundary conditions and interfacial interaction force constants, generated from liquid chromatography experiments.

*Limitations of the Preferential Sorption–Capillary Flow Model:* The PSCF pore flow mechanism has a number of limitations. The assumption of the so-called cylindrical pores in PV membranes and the effect of its size and distribution in the membrane on separation performance of the membrane are not always explainable. In fact the concept of pore size and its distribution in PV membrane is not so important as membrane made by ordinary solution casting method has been found to show reproducible performance. It is not possible to get membranes, always with the same pore size and its distribution by ordinary solution casting coating method and according to PSCF model a slight difference in pore size and its distribution would drastically affect the membrane performance. Similarly, PSCF model cannot explain the simple inverse relation of flux and membrane thickness, membrane swelling, and trade-off relationship between flux and selectivity. According to this model an asymmetric membrane made by phase inversion technique would be the most ideal PV membrane. However, this membrane has not been found to give better performance than the prevailing PV membranes made by ordinary solution casting method [31].

### 5.2.1.2 Solution Diffusion Model

The solution diffusion model is the most widely used model to describe permeation in dense membranes, as is the case for PV [3,32]. This model is based on the following assumptions:

1. Sorption of the feed liquid mixture in the membrane (upstream side) as per the sorption behavior of the solute(s)/polymer system
2. Diffusion of the solutes through the membrane under an activity gradient
3. Desorption of the permeants at the downstream side in the vapor phase

The first two steps, i.e., sorption and diffusion are dominant contributors for separation of the mixture by PV. Desorption of the permeant vapor in the permeate side under low pressure (applying vacuum) is very fast and unlike pore flow mechanism does not offer significant resistance to the transport of the solute.

#### 5.2.1.2.1 Sorption in the Membrane

##### 5.2.1.2.1.1 Sorption Selectivity and Membrane Polymer

Relative sorption of the permeants in the membrane depends on the interactions between the solutes and the membrane polymer. Solubility or miscibility of a component with the membrane polymer depends on their relative solubility parameter values. For mutual solubility of two components their free energy of mixing,  $\Delta G_m$  should be negative.

$\Delta G_m$  is defined as

$$\Delta G_m = \Delta H_m - T\Delta S_m \quad (5.3)$$

Enthalpy of mixing,  $\Delta H_m$ , can be correlated to cohesive energy density, i.e., solubility parameter ( $\delta$ ) as

$$\Delta H_m = n_1 n_2 V_1 (\delta_1 - \delta_2)^2 \quad (5.4)$$

In Equation 5.4, the solubility parameter is that due to only dispersive force between structural units of the concerned solute and polymer since the original Regular solution theory of Scatchard and Hildebrand was restricted to nonpolar, non-hydrogen bonding solutes–polymer systems. However, for many liquid and amorphous polymers, contribution from polar forces and hydrogen bonding [33] need to be considered. Accordingly, Equation 5.4 becomes

$$\Delta H_m = n_1 n_2 V_1 [(\Delta\delta_d)^2 + (\Delta\delta_p)^2 + (\Delta\delta_h)^2] \quad (5.5)$$

From Equations 5.3 and 5.4, it is clear that to make  $\Delta G_m$  negative, the difference between  $\delta_1$  (solvent) and  $\delta_2$  (polymer), i.e.,  $(\Delta\delta)$  for all the three forces of interactions should be as small as possible. It implies that the membrane polymer and the desired component to be separated should be of comparable polarity to achieve similar solubility parameter values. This will result in preferential sorption of the desired component in the membrane.

#### 5.2.1.2.1.2 Sorption and Nature of Membrane Polymer

*Ideal Case:* If sorption process is ideal, the concentration of a component  $i$ ,  $C_{mi}$  in the membrane is linearly proportional to the concentration of this component in the feed mixture,  $C_{bi}$ .

From Henry's law for dilute solutions,

$$C_{mi} = kC_{bi} \quad (5.6)$$

$k$  denotes the sorption coefficient for the solute in the polymer. This relationship holds good for sorption of a component present in trace amounts in a solution (dilute solutions) and when specific interactions between the solute and polymer are absent. However, in most of the cases membrane phase concentration of a component is not a linear function of its bulk concentration. Further, it is also influenced by the presence of the other components.

#### 5.2.1.2.1.3 Sorption Isotherms

Rogers [34] described four different types of sorption isotherms. For very dilute feed solution sorption isotherm is linear obeying Henry's law (Equation 5.6). It is also called type-I sorption isotherm.

For polymeric membranes filled with absorptive fillers, sorption in the filler occurs in accordance with the Langmuir adsorption isotherm while Henry's law governs that in the polymer matrix. This kind of sorption isotherm is designated as type-II isotherm.

For polymers with high degree of crystallinity, and stiff and inflexible chains along with strong cohesive force; type-III sorption isotherm is observed. In this case, the mutual interaction of the sorbed molecules is greater than their interaction with the polymer. Thus, these molecules forms cluster within the polymer matrix.

Type-IV sorption isotherm is a combination of type-II sorption at low concentration and type-III sorption at high concentration. Type-V isotherm as defined here (Figure 5.1) is exhibited by glassy polymers/polymers containing adsorptive fillers. This type of sorption is defined as dual mode sorption, which is a combination of Henry's type and Langmuir type. The former applies to the bulk polymer and the latter to the filler/micro-voids in the polymer. Netke et al. [35] have studied the permeation of acetic acid–water mixtures in silicalite filled PDMS. Equations governing type-V isotherm are

$$C_T = C_M + C_Z \quad (5.7)$$

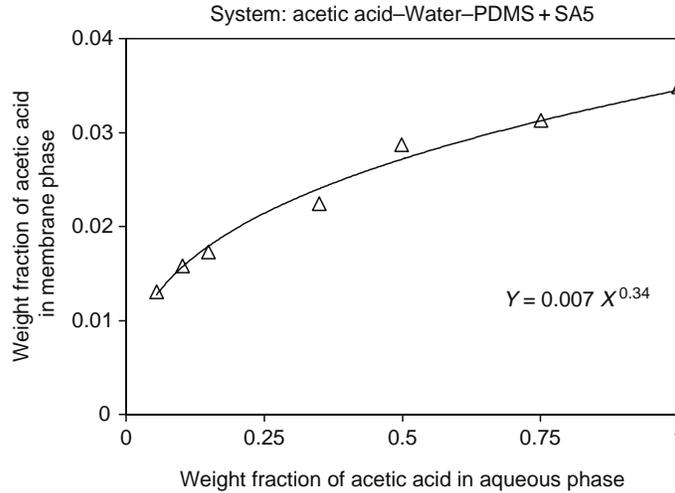

$C_M$  is given by

$$C_M = H_M C_b \quad (5.8)$$

And  $C_Z$  is given by

$$C_Z = \frac{C^* k_Z C_M}{1 + k_Z C_M} \quad (5.9)$$

Figure 5.1 shows the sorption isotherm data of Netke et al. [35] for acetic acid–water–PDMS containing 20% silicalite SA-5 (UOP) converted to the form given by Equation 5.7.

**FIGURE 5.1** Dual mode sorption isotherms. (From Netke, S.A., Sawant, S.B., Joshi, J.B., and Pangarkar, V.G., *J. Mem. Sci.*, 107, 23, 1995.)

#### 5.2.1.2.1.4 Sorption of Single Component in Amorphous Polymers

Sorption of a pure component  $i$  in a membrane of amorphous polymer may be described by the Flory–Huggins [36] equation:

$$\Delta\mu = RT \ln(1 - \Phi_p) + \Phi_p(1 - 1/n_i) + \chi_{ip} \Phi_p^2 = 0 \quad (5.10)$$

where

$n_i$  is the ratio of molar volume of polymer to solute  $i$

$\Phi_p$  is volume fraction of the polymer

The membrane phase concentration of  $i$ , i.e.,  $1 - \Phi_p$  may be calculated from Equation 5.10 provided interaction parameter,  $\chi_{ip}$ , is known.

#### 5.2.1.2.1.5 Sorption of Binary Liquid in Amorphous Polymer

If interaction parameters are concentration independent, in the simplest case [36],

$$\ln(\Phi_1/\Phi_2) - \ln(V_1/V_2) = (1 - 1/n) \ln(\Phi_1/V_2) - \chi_{12}[(V_1 - V_2) + (\Phi_2 + \Phi_1)] - \Phi_3(\chi_{1,3} - \chi_{2,3}) \quad (5.11)$$

#### 5.2.1.2.1.6 Sorption of Pure Component in Cross-Linked Polymer

Cross-links retard swelling and thus decrease concentration of the permeants in the polymer matrix. Effect of cross-linking on the sorption of low-molecular weight components in polymers can be obtained by Flory–Huggins thermodynamics [36]

$$\ln(1 - \Phi_p) + \Phi_p \left(1 - \frac{1}{n_i}\right) + \chi_{ip} \Phi_p^2 + \frac{V_i \rho_p}{M_c} \left(\Phi_p^{1/3} - \frac{\Phi_p}{2}\right) = 0 \quad (5.12)$$

where

$M_c$  is the molecular weight between two cross-links

$\rho_p$  is the polymer density

#### 5.2.1.2.1.7 Sorption of Pure Liquid in Semicrystalline Polymer

The crystallites are impermeable to penetrants leading to a hindered diffusion (tortuosity effect). For a semicrystalline polymer, sorption of pure liquid is given by [36]

$$\ln(1 - \Phi_p) + \Phi_p \left(1 - \frac{1}{n_i}\right) + \chi_{ip} \Phi_p^2 + \frac{V_i \rho_p}{M_v} \left[ \frac{\frac{\Delta H_f}{R} \left(\frac{1}{T} - \frac{1}{T_m}\right)}{\frac{3}{2} \lambda \Phi_p} \right] = 0 \quad (5.13)$$

where

$\lambda$  is the fraction of noncrystalline polymer, i.e., elastically effective

$M_v$  is the molecular weight of the repeating unit of the polymer

$\Delta H_f$  is the heat of fusion of the polymer

$T_m$  is melting temperature of the crystalline phase

The affinity of the solute for the polymer is judged from the value of the interaction parameter. A low value of  $\chi$  indicates greater affinity between the solute and the polymer. It is relatively very easy to measure single component,  $\chi$ , by carrying out sorption experiments and using the experimentally measured sorption data in Equations 5.11 through 5.13 as the case may be. For a binary mixture the values of  $\chi$  so obtained for the two components can be used to ascertain the relative sorption of the two components by the given polymer.

#### 5.2.1.2.2 Diffusion

Similar to sorption, diffusion is also important in determining the separation characteristics of a membrane in that difference in diffusion rate through a membrane gives a permeate rich in one of the component. The diffusion coefficient of a permeant through a polymer is a strong function of the size and shape of the permeant. In a homologous series, molecules with low molecular weight will move faster. When molecular weight and chemical nature are the same, molecules with smaller cross-section diffuse faster. However, sorption has a strong bearing on diffusion. High sorption always results in higher rates of diffusion as explained below:

1. An increase in the concentration of the permeant in the polymer swells it and promotes the free rotation of the polymer segments about the chain axis resulting in lower activation energy for diffusion.
2. In PV, the amorphous region is responsible only for permeation and on sorption, this region in the polymer swells—thus more free volume becomes available for permeation.
3. When the membrane is highly sorbed, a major part of the polymer matrix contains the liquid permeants and diffusion of the incoming permeant through this “liquid zone” of the solid polymer is faster than through the dry solid polymer.

##### 5.2.1.2.2.1 Single-Component Diffusion

The diffusion coefficient is a strong function of concentration. Long [37] expressed it as an exponential function of concentration

$$D_i = D_{i0}e^{(A_i C_i)} \quad (5.14)$$

$A_i$  is the plasticization coefficient to account for interaction of the particular permeant and polymer. It represents the magnitude of the effect of solvent concentration on solvent mobility in the membrane.

Greenlaw et al. [38] proposed another relationship between diffusivity and concentration:

$$D_i = D_{i0}(1 + A_i C_i^n) \quad (5.15)$$

and found that the following simplified expression

$$D_i = kC_i \quad (5.16)$$

fitted the data from Rogers et al. [39] up to a vapor phase activity of 0.5 for diffusion of hexane in polyethylene membranes. In their analysis for single-component permeation, Rautenbach and Albrecht [40,41] used a modified form of Greenlaw and coworker's equation with the exponent  $n$  equal to unity.

$$D_i = D_{i0}(1 + A_i C_i) \quad (5.17)$$

##### 5.2.1.2.2.2 Multicomponent Diffusion

Diffusion in multicomponent system is difficult to analyze. Transport of one component is affected by the presence of the other component due to their mutual interaction. This results in the coupling of fluxes. Thus, single-component diffusion equation cannot be used to predict diffusion in a multicomponent system. Greenlaw et al. [38] proposed a simple relationship in which the diffusion coefficients for components  $i$  and  $j$  are interdependent on both component concentrations:

$$D_i = k_{di}(C_i + B_{ij}C_j) \quad (5.18)$$

and

$$D_j = k_{dj}(C_j + B_{ji}C_i) \quad (5.19)$$

Shelden and Thompson [42] used the following equation while modeling PV of toluene/ethanol mixture with polyethylene membrane, and water/ethanol with both homogeneous and asymmetric PVA membranes.

$$D_i = D_{i0} + k_{di}(C_i + B_{ij}C_j)^{ki} \quad (5.20)$$

and

$$D_j = D_{j0} + k_{dj}(C_j + B_{ji}C_i)^{kj} \quad (5.21)$$

Brun et al. [43] described binary pervaporative transport using an exponential diffusion model that is dependent on individual component concentrations:

$$D_i = D_{i0} \exp(A_{ii}C_i + A_{ij}C_j) \quad (5.22)$$

and

$$D_j = D_{j0} \exp(A_{jj}C_j + A_{ji}C_i) \quad (5.23)$$

This model includes the mutual coupling effect of the permeants. A positive or negative value of  $A_{ii}$  or  $A_{ij}$  indicates a positive or negative effect of the presence of one component on the transport of the other component. Sferrazza et al. [44] have analyzed the behavior of binary systems using an approach similar to that of Brun et al. [43]. They used a similar model to describe diffusion:

$$D_i = D_{i0} \exp[(A_i(C_i + B_{ij}C_j))] \quad (5.24)$$

and

$$D_j = D_{j0} \exp[(A_j(C_j + B_{ji}C_i))] \quad (5.25)$$

The interaction coefficients give an indication of the extent of coupling in the membrane.

#### 5.2.1.2.2.3 Transport Equation through Membrane

The permeation of component  $i$  through the membrane can be described by Ficks' first law as

$$J_i = -D_i \frac{dC_i}{dx} \quad (5.26)$$

As mentioned earlier, the diffusion coefficient is a function of membrane phase concentration of the permeants. Hence Equation 5.26 yields:

$$J_i = -D_{i0} f(C_i) \frac{dC_i}{dx} \quad (5.27)$$

where  $D_{i0}$  is the diffusion coefficient of component  $i$  at infinite dilution. Integrating Equation 5.27 over the entire membrane thickness  $L$  assuming that the variation in  $D$  along the membrane thickness is accounted by the first two terms on the right-hand side of Equation 5.27, the equation reduces to

$$J_i L = -D_{i0} \int_{C_{fi}}^{C_{pi}} f(C_i) C_i dC_i \quad (5.28)$$

Membrane phase concentration of component  $i$  in the feed side,  $C_{fi}$ , can be calculated from its bulk concentration by Henry's equation (Equation 5.8) provided it is present in trace amount in the feed solution. For higher concentration of component  $i$ ,  $C_{fi}$  can be obtained from experimental sorption data. Membrane phase concentration on the permeate side of component  $i$ , i.e.,  $C_{pi}$  may be neglected due to the low pressure the activity of the component in the downstream side is very low. Thus, Equation 5.28 can be readily solved to calculate the theoretical flux and diffusion coefficient of  $i$  or  $j$  component employing any of the above equations relating the diffusion coefficient and concentration, Equations 5.14 through 5.25 depending on its best matching with the experimental data.

## 5.2.2 CONCENTRATION POLARIZATION AND PERMEATION

Concentration polarization (CP) of the permeants and its resistance to permeation through the membrane is encountered in most membrane processes. In an ideal case, in the absence of any CP, the concentration of the permeants should not change from

bulk-feed to membrane-feed interfaces. However, due to fluid viscosity (shearing action between two successive liquid layers opposing their relative velocity) there is a decrease in velocity of the permeants from bulk-feed to the stationary membrane surface where the velocity of the fluid is zero. Thus, the concentration of the permeant at the membrane interface becomes lower than that in bulk-feed. In the case of UF, MF, or RO, the retained solute on the membrane surface may cake out (when its concentration exceeds its solubility product) and thus choke the membrane pores and as it accumulates more and more, a diffusive back flow from membrane phase to bulk liquid is developed. These are accompanied by a decreased flux with time. In the case of pervaporation, CP is not so important due to relatively low permeation rates experienced in these dense membranes. Further, unlike UF, RO, or MF, none of the permeants is retained on the membrane surface. In PV all of the permeants pass through the membrane by a solution–diffusion mechanism. However, in these membrane processes CP becomes significant, when the membrane is very thin and highly selective to one of the permeants present in very low concentration (e.g., removal of traces of volatile organic compound from its aqueous feed). In this case, the rate of permeation of this permeant through the membrane becomes much faster than its rate of supply from bulk-feed to the feed-membrane interfaces resulting in CP for this permeant. However, in the case of PV, on the downstream side no such CP occurs due to very large values of the gas phase diffusion coefficient.

In industrial application, a thin PV membrane on a UF porous support membrane is generally employed. Thus, the concentration gradient on the feed side cannot be ignored. By assuming boundary layer resistance in series with membrane resistance the following equation [29,45] may be derived:

$$\frac{1}{K_o} = \frac{1}{k_L} + \frac{L}{D \cdot S} \quad (5.29)$$

where

$K_o$  is the overall mass transfer coefficient

$k_L$  is the mass transfer coefficient for the boundary layer

$S$  is the sorption coefficient defined as the ratio of the membrane phase concentration and feed phase concentration ( $C_M/C_F$ )

$L$  is the membrane thickness

The product  $D \cdot S$  is the intrinsic permeability that can be obtained from experimentally determined values of  $D$  and  $S$  or through experiments at very high levels of turbulence such that the boundary layer resistance is eliminated ( $K_o = L/D \cdot S$ ). A number of correlations are available in the literature for reliable estimates of  $k_L$  for various geometries of the modules [29,45].

Sufficient turbulence at the membrane surface is required to eliminate CP. In PV fluxes are measured at different turbulence rates in the feed side are determined till a constant flux is achieved. At this turbulence, the rate of mass transfer in the membrane phase boundary layer may be assumed to be eliminated ( $k_L \gg D \cdot S/L$ ). Proper hydraulic management on the feed side generally eliminates CP. However, for very dilute solutions where the driving force for the fluid-membrane mass transfer process is relatively very low, CP cannot be avoided. In addition to CP, temperature polarization may also affect the overall flux. This is due to the fact that the enthalpy of vaporization of the solute in the permeate compartment is supplied by the hot feed. The hot fluid transfers sensible heat to the membrane (by convection) which in turn supplies it by conduction to the permeate side of the membrane. This is also a case of resistances in series and an equation similar to Equation 5.29 can be written. When the supply of sensible heat from the bulk-feed side to the membrane is much less as compared to the heat required to vaporize the solute in the permeate compartment, temperature polarization develops. Thus, there is a drop in temperature from the bulk-feed to the membrane surface. This phenomenon is termed “temperature polarization” similar to its mass transfer counterpart, in concentration polarization Mulder [29] has given detailed description of both these phenomena and methods of tackling them. In particular the loss of sensible heat by the feed stream must be compensated. This is generally achieved by employing interstage heat exchangers.

In the PV mode the feed side is in contact with a liquid, which tends to sorb in the polymer and swell it. As the solute(s) diffuse across the membrane at the permeate side face of the membrane, the solutes are vaporized. Thus, the membrane exhibits different structures from the feed to the permeate side. The former is wet and swollen and hence yields high diffusion rates. The downstream part being fairly dry affords much lower diffusion coefficients than the swollen feed side. The assumption of a diffusion coefficient independent of the distance inside the membrane in Equation 2.38 is therefore not rigorously correct.

### 5.2.3 SELECTIVITY IN PERVAPORATION

The overall selectivity in PV  $\alpha_o$  is determined by (1) sorption and (2) diffusion selectivities.

Sorption selectivity,  $\alpha_s$ , can be defined as the ratio of the sorption coefficient for solutes A and B in a binary mixture:

$$\alpha_s = \frac{S_A}{S_B} \quad (5.30)$$

Diffusion selectivity,  $\alpha_D$ , can also be similarly defined as the ratio of the two diffusion coefficients:

$$\alpha_D = \frac{D_A}{D_B} \quad (5.31)$$

The overall selectivity,  $\alpha_o$ , is given by

$$\alpha_o = \alpha_S \times \alpha_D \quad (5.32)$$

Another parameter used to define the selectivity of a membrane is the separation factor,  $\beta$ :

$$\beta = \frac{C_{Pi}}{C_{Fi}} \quad (5.33)$$

where  $C_P$  and  $C_F$  are the concentrations of the selectively permeating solute  $i$  in the permeate and feed, respectively.

In general, for PV  $\alpha_S$  is the dominating contributor to  $\alpha_o$  and most membranes are designed to achieve high values of  $\alpha_S$  [21,25]. However, in some cases although  $\alpha_S$  is favorable,  $\alpha_D$  is not and in such cases  $\alpha_o$  is poor [28].

The pervaporation separation index (PSI) indicates the overall productivity of PV membrane:

$$\text{PSI} = J_i \times \beta \quad (5.34)$$

## 5.3 MEMBRANE FABRICATION METHODS AND MEMBRANE MODULES

### 5.3.1 INTRODUCTION

The membrane is the heart of any membrane-based separation processes. The initial breakthrough in the membrane technology came from the phase inversion technique, developed by Loeb and Sourirajan [46]. The membrane prepared by adopting the phase inversion technique became the first commercial UF membrane and the membranes prepared by this technique are finding widespread use in industrial separations. A second breakthrough in the membrane development occurred in the early 1970s. That was the thin film composite (TFC) membrane made by interfacial polymerization technique pioneered by Cadotte et al. [47]. It is now a well-established method for preparing defect-free membranes only a fraction of a micron in thickness from a variety of polymeric materials particularly for UF and RO. Development of composite membranes, in 1980s by Brusckie et al. [48], allowed the transformation of PV process from laboratory to industrial scale. The German company GFT reported the first commercial use of membranes in pervaporation. This section covers the various methods used for making PV membranes and corresponding modules.

### 5.3.2 IDEAL MEMBRANE FOR PERVAPORATION

An ideal pervaporation membrane should consist of an ultra thin defect free skin layer (dense layer) supported by a porous support. The skin layer is perm-selective and hence responsible for the selectivity of the membrane. However, the porous support also plays an important role in overall performance of the membrane. The effect of the porous support, of a composite membrane, on the permeation properties of the membrane is discussed in details in the composite membranes section.

Ideal pervaporation membrane should possess the following characteristics:

1. The top layer/skin should be as thin as possible and without any defects.
2. It should exhibit high sorption and diffusion selectivities for the desired solute when contacted with a mixture containing it.
3. It should not swell excessively to maintain the selectivity and structural stability.
4. It should possess good mechanical strength, chemical and heat stability.
5. It should offer high fluxes without compromising selectivity.

Quantitatively the performance of a PV membrane can be described by the PSI defined by Equation 5.34. A higher value of PSI indicates better overall productivity. In view of the various advantages of PV there is considerable research interest in developing suitable membranes for different applications. The efforts in this direction are not limited to the academic sector.

The industrial sector has also made significant contributions with companies, such as Sulzer ChemTech, Membrane Technology and Research (MTR), USA; Mitsui Engineering, Ube (Japan) leading the field. Different factors that have a major impact upon membrane morphology are listed below:

1. Choice of polymer
2. Viscosity of casting solution
3. Curing temperature
4. Glass transition temperature ( $T_g$ ) of the polymer

Amongst these the choice of the polymer is the most important since it decides the sorption selectivity for the solute of interest. The methods adopted to prepare PV membranes can be broadly classified into three types:

1. Phase inversion
2. Coating of the perm-selective polymer skin on a UF support
3. Other types

Amongst these, membranes prepared by phase inversion technique are generally used for UF and RO processes. Theoretically, phase inversion process can be used to prepare a dense top layer (perm-selective layer) on a porous support of the same polymer. This is achieved by proper selection of the polymer-solvent and precipitating bath composition so as to allow a delayed de-mixing process during the phase inversion process. Mulder [29] has discussed the relevant thermodynamic aspects of selection of the polymer-solvent-non-solvent bath compositions in detail. The phase inversion technique is, however, not very popular for making PV membranes. On the other hand, membranes prepared by the phase inversion technique are invariably used as the porous support to prepare composite membrane by the polymer solution coating process. Composite membranes prepared by this coating method are most widely used as PV membranes. The major advantage of this type of membranes is that the perm-selective polymer coating and the polymer for the UF support can be selected independent of each other's physical properties. The only requirement is that the two polymers should form a strong bond to prevent the peeling out of the skin layer from the support membrane. The techniques for making composite membranes are discussed briefly in the following sections.

### 5.3.3 COMPOSITE MEMBRANES

For industrial applications, where the membrane sizes are larger, reinforcement of the thin skin membrane by an appropriate support is required to maintain dimensional stability. This type of membrane consisting of a skin layer (perm-selective layer) supported by a suitable support is called a composite membrane.

#### 5.3.3.1 Importance of the Support Layer

The support membrane has a strong influence on the performance of the perm-selective skin layer. Heinzelmann [49] has given the consequences of the various types of support defects leading to change in permeation properties of the composite membranes. Recently, Trifunovic and Tragardh [50] have studied the role of the support layer of a composite membrane in PV. Although the mass transport of permeants through the active, dense layer is the rate-determining step, the support layer can also be a contributor to the overall mass transport resistance, especially in the case of components which, under the operating conditions employed, can condense/vaporize due to small variations in the pressure. The support layer used for pervaporation membranes is usually an asymmetric ultrafiltration membrane. There is a variation in the pore diameter across the thickness of such an asymmetric membrane. Next to the dense layer the pore diameter in the support is relatively very small. The pores widen as the solute diffuses across the support. At the permeate side face the support has the largest pores. A simple model for the porous support is that of a bundle of straight cylindrical capillaries. The type of flow in a pore depends upon the relative size of the pore and the mean free path of the molecules involved. When the mean free path is much smaller than the pore diameter, viscous flow prevails. In such a case the support layer does not create any serious impediment to mass transport. However, if the pores are smaller than the mean free path, Knudsen diffusion, which has a much lower rate, can cause significant reduction in the overall mass transport. In these pores, the local vapor pressure can exceed the critical condensation pressure resulting in capillary condensation. Rautenbach and Albrecht [51] have indicated that in such a case a part of the pore length contains the solute(s) in liquid form and the remaining part only contributes to the evaporation process. Thus, in case of capillary condensation there is a reduction in membrane selectivity due to the decrease in the driving force for pervaporation. The Kelvin equation can be used to predict the critical (partial) vapor pressure at which condensation occurs in the pore:

$$P_i^C = P_i^0 \exp\left(-\frac{4\sigma_p V_i}{d_{\text{pore}} RT}\right) \quad (5.35)$$

Trifunovic and Tragardh [50] in their study of PV of homologous series, alcohols, and esters using POMS membranes with different supports derived the following general conclusions:

1. Larger molecules with lower Knudsen diffusion coefficients suffer higher loss in selectivity.
2. Solutes with low vapor pressures (easily condensable) suffer greater loss in selectivity due to the pressure build-up in the Knudsen capillaries.
3. The capillary inside surface also affects the composite membrane performance. For alcohols with hydrophilic OH groups it is desirable to have a hydrophobic capillary surface.
4. To avoid the detrimental effects mentioned above the Knudsen capillaries should be as short as possible.

### 5.3.3.2 Techniques for Fabrication of Composite Membranes

Following methods can be adopted to prepare composite membranes used for pervaporation.

#### 5.3.3.2.1 Direct Coating

Heinzlmann [49] and Briston [52] have given details of these methods. The main problem with direct coating is that incompatibility of the porous support with polymer solution can result in the formation of pinholes in the membranes. However, this problem can be overcome if care is taken to ensure sufficient wetting of the support by the polymer solution. Parameters that can be varied in optimizing the process for a defect free membrane are

1. Pretreatment of the support prior to coating
2. Optimization of composition, viscosity, and surface tension of the polymer solution

Choice of appropriate coating method along with drying/curing conditions can yield a stable defect-free membrane.

#### 5.3.3.2.2 Interfacial Polymerization

Interfacial polymerization provides another method for depositing a thin layer upon a porous support [47,49]. In this case polymerization occurs between the two reactive monomers at the interface of the two-immiscible solvents. Heat treatment is often applied to complete the interfacial polymerization, to cross-link water-soluble monomer or prepolymer. The advantage of this technique is that the reaction is inhibited by the passage of a limited supply of reactants through the already formed polymer layer, resulting in extremely thin film of thickness in the range of 1–2 nm. Such membranes are therefore referred to as thin film composites. TFCs of various poly(amides) are very popular in RO applications.

#### 5.3.3.2.3 Radiation-Induced Formation of Composite Membranes

The radiation-initiated grafting of polymer films (i.e., radiation-induced grafting), radiation-initiated curing of thin film coating on porous supports (i.e., radiation cured composite membrane), and coating of porous substrate by plasma polymerization (i.e., plasma chemical processes) are an alternative method to prepare nonporous flat sheet PV membranes. Specific sorption capability for distinct solutes is achieved by introducing different functional groups, which show specific interactions with the solute onto the polymer backbone of supporting substrate [53–55].

#### 5.3.3.2.4 Transfer Coating

Details of this method for transfer coating or lamination of perm-selective skin on a porous support can be found in the literature [49,52]. First, the advantage of this method is that a definite predefined skin layer thickness can be achieved. Second, the problem of insufficient wetting of support by coating solution and incompatibility of the support with solvent can be overcome.

#### 5.3.3.2.5 Other Techniques

In another popular technique the skin layer polymer is independently prepared by means of suitable polymerization techniques, such as formation of copolymers [21], graft [56] and block polymers, polymer blends [57], cross-linked polymer [58], and interpenetrating polymer networks (IPNs) [11] and then coating this polymer solution on the porous support to form a composite membrane for pervaporation application. Membranes prepared by these techniques offer easy tailoring of membrane properties for different applications. As dictated by the sorption diffusion model, a skin layer that has selective but limited sorption should be prepared. Further, membrane strength can be increased by adjusting the crystalline portion (backbone) of the polymer films. Different membranes can be readily prepared according to the application, simply by changing the functional groups of the polymer.

### 5.3.4 PERVAPORATION MODULES

Pervaporation modules have been basically adapted from the module designs already used in other applications, such as RO, NF, and UF. However, the major difference is that in the latter case the applications mainly pertain to treatment of predominantly aqueous solutions. Therefore, the glues, gaskets, etc. to be used do not require any special consideration except

that they should yield a strong bonding. In the case of pervaporation one of the two sides of the module (feed/permeate) is in contact with an organic solvent. This solvent may attack the glue/gasket used. Therefore, selection of the glue/gasket material needs special attention. In the case of dehydration of organics the feed side is in contact with a predominantly organic medium, while for removal of trace organics from water the permeate side has to bear the attack of the organic solvent. Finally, in the case of organic–organic separations both the feed and permeate sides have to be designed properly considering the presence of organics that may have high solvent power. Thus, besides the strength of the bond the solvent resistance of the glue is also important. In view of this the plate and frame module was initially much more popular than the spiral wound module.

Another consideration that is important in pervaporation is the prevention of excessive pressure drop on the permeate side. Too high a pressure drop reduces the flux (also see Section 5.4.3: Importance of support layer). Therefore, to avoid excessive pressure drop, generally the permeate side is kept open directly to the condenser/heat transfer surface.

The economic advantage of pervaporation lies in the fact that particularly for the two extreme applications: dehydration of organics and removal of organics from water, the focus is on the trace quantity. In the case of dehydration of organics a highly water-selective membrane is used. On the other hand, for removal of organic from water an organophilic membrane is used. In both these cases, the solute to be removed is a minor/trace quantity. With this approach the duty of the module (total amount to be removed) is greatly reduced. However, since the solute is present in much smaller quantities in the feed side, concentration polarization can be a serious draw back. To overcome this, the design of the feed side needs some attention. The design to be used should allow rapid mass transfer from bulk liquid to the membrane surface so as to achieve the intrinsic membrane flux. Generally, the flow Reynolds number on the feed side should be sufficiently high so as to overcome concentration polarization. This condition implies a higher power input because of high flow rates on the feed side.

A number of module designs are possible and all are based on the two types of membrane configuration, (i) flat sheet and (ii) tubular. These are plate and frame, spiral wound, tubular, capillary, and hollow fiber.

### 5.3.5 SELECTION OF THE MEMBRANE MODULE

Choice and arrangement of the membrane module in a system is based on economic considerations with the correct engineering parameters being employed to achieve this. Some aspects to be considered are

1. Nature of the separation problem
2. Ease of cleaning
3. Ease of maintenance
4. Compactness of the system
5. Membrane replacement

Depending upon the nature of application and operating conditions the module is selected. Table 5.1 gives a qualitative comparison of the various types of modules available and can be used as a reference guide for module selection.

### 5.3.6 SOME PROBLEMS IN INDUSTRIAL USE OF PERVAPORATION

The major application of PV has been in the dehydration of ethyl and isopropyl alcohols. In both these case severe fouling of the membranes was observed. In the case of ethyl alcohol the fouling was attributed to the rust particles from the mild steel fermenters used. In the case of *i*-propanol the applications were for its recovery from a mixture containing water and dissolved

salts from the washing operations. In this application the membranes developed severe blisters and became useless. These blisters can be traced to the crystallization of the salt in the membrane. Some ingress of the salt cannot be avoided due to the high water sorption in the membrane. The membrane removes water. The water is volatile and is evaporated at the downstream face. The salt, however, cannot do so and is hence trapped in the membrane. As the water is removed the salt introduced in the top layer with the water crystallizes out of the alcohol-rich phase. This is probably the most likely reason for the formation of blisters. Observation of the blisters under a microscope showed presence of solid particles confirming the above postulate. This problem can be overcome by resorting to vapor permeation (VP) rather than PV. Thus, the alcohol stream is boiled to supply a vapor to the membrane module. VP obviously has a higher energy requirement than PV since the liquid needs to be vaporized. Careful design of the reboiler and provision of a mist eliminator prevents any carry over of the salt. Thus a mixture of water and alcohol vapors totally devoid of the salts is supplied to the membrane module. This arrangement has been found to be quite effective in ensuring a longer membrane life.

## 5.4 APPLICATIONS OF PERVAPORATION

As discussed in Section 5.1, PV has applications in all types of separations involving aqueous/organic phases. These are

1. Dehydration of organics
2. Removal of organics from aqueous phase
3. Organic–organic separations

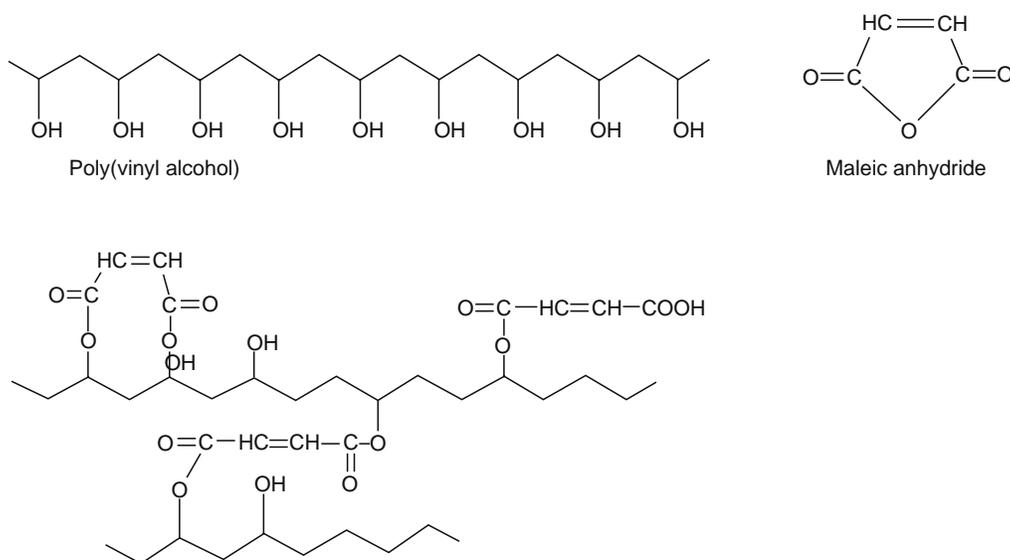

The discussion in Section 5.2 on theory of PV indicates that the membrane polymer to be selected for a given separation should have high sorption affinity for the solute to be removed preferentially. For the first two categories it is relatively easy to choose a polymer. Thus, the following types of polymers are suitable as membranes materials for these two cases: (1) hydrophilic polymers with large contributions due to hydrogen bonding and polar forces to the overall solubility parameter and (2) hydrophobic (organophilic) polymers with major contributions from dispersion forces. These applications are discussed separately in the following sections.

### 5.4.1 DEHYDRATION OF ORGANICS

Most of the commercialization of PV technology occurred in this category for dehydration of ethanol and *i*-propanol. For ethanol, a hybrid system comprising of distillation to remove bulk of the water (enrichment of ethanol from 8 wt% to ~85 wt%) followed by a PV module to reach 99.8 wt% ethanol has been popular. This hybrid system combines the strengths of distillation and PV in their respective areas. In this case generally a small amount of water (<10 wt%) is required to be removed by PV. It is evidently far more economical to focus on the removal of this small water quantity rather than trying to remove the organic. With this logic the membrane polymer selection becomes very easy. Thus, hydrophilic polymers that selectively sorb water are used. Poly(vinyl alcohol), PVA, is a very popular polymer for dehydration of organics. The hydroxyl group in PVA imparts high hydrophilicity to PVA since the OH group has a dominant effect in deciding the properties rather than the relatively small CH<sub>2</sub>=CH alkyl group. However, the high hydrophilicity, which is the strong point in favor of PVA, also turns out to be its weak point. The thin top selective layer made of PVA that is in continuous contact with water-rich solution gradually dissolves and hence the membrane loses its permselectivity. To enhance the active life of such a PVA membrane the polymer is cross-linked by a suitable compound having a functional group that can react with the OH group of PVA. Suitable cross-linkers are carboxylic acids/anhydrides, dialdehydes, etc. Maleic anhydride is reportedly used in the first PVA membrane commercialized by GFT (now Sulzer Chemtech). Cross-linking connects two polymer chains (Figure 5.2) and hinders the dissolution of individual chains that are now bound to other chains through the cross-links. The advantage of extended life gained by the cross-linking is however, offset by the reduced mobility/flexibility of the chains due to the same cross-links. This reduced flexibility of the polymer chains results in a reduction in the diffusion coefficient of the solute and hence the flux decreases (Equation 2.26).

In view of this the cross-linking is moderate. The usual range is about 4%–8% of the total functional groups being cross-linked. This is a case of the classical trade-off between low depreciation due to extended life, and low productivity due to lower flux.

In many cases the organic to be dehydrated (e.g., acetic acid) attacks the ether linkage in the PVA membrane. Indeed, the PVA membrane has very limited life in the presence of most acids. Ray et al. [14] used the concept of copolymer membranes to dehydrate acetic acid over the entire range of concentration from 0% to 100%. These investigators prepared copolymers of acrylonitrile (AN) with different hydrophilic monomers like hydroxy ethyl methacrylate, acrylic acid, methacrylic acid, and itaconic acid. These copolymers have carbon–carbon bonds, which unlike the ether linkage in the cross-linked PVA membrane are stable to the attack by carboxylic acids. The acrylonitrile part is not sufficiently hydrophilic but imparts mechanical strength while the other monomers improve the hydrophilicity. The overall result is an efficient yet stable membrane. Variation of the ratio of AN to (the other) monomer allows freedom of adjusting the hydrophilicity of the membrane to achieve certain

**FIGURE 5.2** Cross-linking of poly(vinyl alcohol) with maleic anhydride.

selectivity and flux. High ratio of the more hydrophilic comonomer to AN increases water sorption and hence flux but results in a concomitant loss in selectivity. Ray et al. [14] showed that this concept of copolymer membrane yields a low-cost alternative to the more expensive hydrophilic polymers like Nafion and polyimide.

Another interesting application of hydrophilic membranes is in esterification reactions. These reactions are generally equilibrium limited. High conversions (low acid numbers) are possible when the equilibrium is displaced by removal of the water formed in the reaction. Distillation has been a popular method for water removal. However, hydrophilic membranes in the PV mode are an attractive alternative because of the high selectivities and low-operating cost. Brusckhe [59] has described the details of the first continuous industrial plant combining PV with an esterification reaction employing a cascade of reactors and PV units. A simple mathematical model described can be used to calculate the optimum membrane area per unit mass of the reaction mixture. The kinetics of the esterification reaction required for use in this model are either available in the existing literature or can be obtained using standard laboratory techniques for measurement of kinetics.

Another very promising application of PV is in dehydrating glycerin. Glycerin is mainly produced as a by-product in the fat splitting process for manufacturing fatty acids. The scale of operation is quite large (~300 t/day of fatty acids). The glycerin is produced as a weak (~10–15 wt%) aqueous solution referred to as sweet water. Conventionally it is converted to anhydrous glycerin using distillation. The low decomposition temperature of glycerin necessitates distillation under high vacuum. Even with this distillation under high vacuum some degradation of glycerin cannot be prevented. PV can be an ideal low energy alternative to distillation [12,60]. It has been shown [60] that PV can yield selectivities 1000 times higher than the corresponding distillation selectivity at temperatures as low as 70°C.

Table 5.2 lists the various hydrophilic polymers used for dehydration applications. Table 5.3 gives a comprehensive coverage of the available literature on dehydration of organics. It is evident from Table 5.3 that this application is the most widely investigated class of PV. Further, as mentioned in Section 5.1 this category has seen the most significant commercial utilization amongst the three categories listed earlier. Further there are other potential large-scale applications yet to be

System	Membrane Used	Remark	Reference
Ethanol (water)	Cross-linked PVA	$\beta = 260$ at 75°C for 50% aqueous ethanol solution	[61]
Phenol (water)	PVA-PAA Cross-linked	$\beta = 3500$ for aqueous phenol solution	[62]
Phenol (water)	Cross-linked PVA (PAA = 80/20)	$\beta = 2580$ at 70°C for 80% aqueous phenol solution	[63]
Ethylene glycol (water)	Partially hydrolyzed polyacrylonitrile/1-poly(acrylic acid) blend layer membrane	An 85:15 (wt%) ethylene glycol:water solution was separated by pervaporation to give 25:25 ethylene glycol:water permeate at 70°C	[64]
Ethanol (water) and propanol (water)	Regenerated cellulose and cross-linked PVA membrane	$\beta = 3500$ for aqueous ethanol solution and $\beta = 6000$ for aqueous IPA solution	[65]
EtOH, MeOH, iso-PrOH, dioxane or EtOAC (water)	PVA membrane	Total flux decreases with increasing permeate pressure	[66]
Methanol (water)	Cross-linked PVA membrane	$\alpha = 2650$ for PVA/PAA = 80/20 and 465 for PVA/PAA = 90/10	[67]
Organic aqueous and organic-organic binary mixture	Silicone grafted polymers, styrene fluoroacrylate copolymers silicate filled silicone films	Pervaporative separation of organic-aqueous and organic-organic liquid mixture with different membranes is studied	[68]
Methanol (water separation)	Hybrid PV + distillation	A review on dehydration of solvents in the fine chemical industry	[69]
Alcohol mixture (water)	Polyelectrolyte multilayer membrane	Best results are obtained when temperature is raised from 25°C-80°C. A membrane with double layers yielded $\beta = 900$	[70]
Dehydration of isopropanol/water	Polymeric (PERVAP 2510, Sulzer Chemtech GmbH) and Ceramic membranes (NaA type zeolite, Mitsui & Co.)	Traditional azeotropic distillation was compared with a hybrid system consisting of distillation followed by pervaporation and a hybrid system consisting of distillation followed by pervaporation followed by a second distillation	[71]
Dehydration of acetic acid, alcohols, and acetone by pervaporation	Acrylonitrile-maleic anhydride copolymer membrane	The membrane exhibits reasonable performance with respect to both separation factor and permeance (11.0 and 279.4 g/m <sup>2</sup> h/bar, respectively, at 92 wt% feed conc. of water) for acetone dehydration	[72]
Dehydration of IPA	Hybrid PV-distillation processes intensification	Hybrid process economics	[73]
1-methoxy propanol-water	Polyimide (PI), cellophane, poly(vinyl alcohol) (PVA), cellulose diacetate (CDA), cellulose triacetate, two separate blends of cellulose acetate and CDA with cellulose acetate propionate, and PVA cross-linked with multifunctional cross-linkers	The effects of different substitution derivatives of cellulosic materials were investigated	[74]
1-methoxy propanol-water	Acrylonitrile-based copolymer membrane	The copolymer properties, in particular, solubility parameter, component group contribution, and interaction parameter values are used to explain perm-behavior (selectivity and flux). Copolymers of AN showed good selectivity with reasonable flux	[15]
Dehydration of organic liquids	Water-selective membrane	Some perm-selective membranes and separation processes are introduced	[75]
Dehydration of organic liquids	Aromatic polyamide membrane	Effect of type of diamine on water selectivity studied (Japanese)	[76]
Separation of water/acetone mixture	Acrylamide-acrylic acid copolymer gel prepared in porous of ceramic thin membrane	Controlled cross-linking gives very high selectivity for water	[77]
Organic-organic and organic compounds/water separation	Acrylonitrile-vinyl compounds copolymer membrane	$\alpha = 1747$ for 80% aqueous acetic acid at 70°C	[78]
H <sub>2</sub> O/organic separations	Copolymers of peptides/proteins having amino groups with acrylonitrile	High permselectivity for water reported	[79]
Dehydration of organic liquids	Hydrophilic polymer membranes	Mass transfer analysis of pervaporation	[80]

**TABLE 5.3 (continued)**

System	Membrane Used	Remark	Reference
Dehydration of organic solvents	Plasma or electric beam induces graft polymer and cellulose membrane	A review with 25 references on recent progress in the preparation of pervaporation membranes for the H <sub>2</sub> O/organic solvent separation including dehydration, selective separation of EtOH, and solvent removal or recovery from effluents	[81]
Water + methanol, ethanol, <i>n</i> -propanol, isopropanol, <i>n</i> -butanol and isobutanol	PVA cross-linked with a multifunctional cross-linker	The activation energy of diffusion for water was found to vary with water–alcohol systems in the range 20–50 kJ mol <sup>-1</sup>	[10]
Enzymatic esterification of oleic-acid and <i>i</i> -amyl alcohol	Hydrophilic membrane for water removal	Influence of pervaporation process parameters on enzymatic catalyst deactivation is studied. Below a certain level of water concentration, enzymatic catalyst activity is very low. On the other side, high initial concentrations of alcohol deactivate the catalyst	[82]
Lipase-catalyzed enantioselective esterification of racemic ibuprofen coupled with pervaporation	A cross-linked poly(vinyl alcohol) (PVA) membrane and commercially available per fluorinated membranes (Nafion 117 and Nafion NE 450)	Effects of the reaction temperature, the concentration and nature of alcohol on the reaction rate and enantioselectivity were investigated systematically with and without pervaporation. The PVA pervaporation membrane appeared to be more suitable for the enantioselective esterification of ibuprofen than the Nafion membranes	[83]
Pervaporation separation of an aqueous organic mixture	Poly(acrylonitrile- <i>co</i> -vinyl phosphonic acid) membrane	High selectivity toward water. PANVA membrane exhibited 99.8% H <sub>2</sub> O concentration on permeate side in case of pyridine–H <sub>2</sub> O mixture	[84]

explored. This use of hydrophilic membranes to remove water in esterification or similar equilibrium limited reactions can be used conveniently to reach practically 100% conversion to the product. However, in most such cases an acid is used as a catalyst and the conventional PVA-based membranes are easily attacked leading to short lives. The copolymer membranes proposed by [14] can be used in these applications since C–C bond is not prone to attack by acids. Alternatively ion exchange (H<sup>+</sup> form) resins can be used as catalyst if it is decided to employ the PVA-based membranes. This possibility has however, not been tested commercially.

#### 5.4.2 REMOVAL OF ORGANICS FROM AQUEOUS PHASE

These classes of application deals with removal of trace organics from a predominantly aqueous body. Several organic chemicals have solubilities in water sufficient to reckon both in terms of the potential economic loss and pollution. The solubilities are too low to be dealt with by distillation since distillation is expensive. PV is an ideal alternative in this case. In stark contrast to distillation wherein the selectivities are in single digits, PV can yield several orders of magnitude higher selectivities [16,18,20] resulting in very high recovery of the dissolved organics at much lower cost. The selectivities can be further improved albeit at a loss of flux by incorporating hydrophobic fillers in a hydrophobic membrane. Netke et al. [36] developed a comprehensive dual mode model for permeation in membranes containing adsorptive fillers. The model proposed can predict the effects of various parameters like adsorbability of the solute and loading of the filler. The proposed model also correctly describes the asymptotic behavior of such membranes.

The polymers used for this class of application are listed in Table 5.4. Although the other polymers listed in Table 5.4 are easily available and less expensive, the standard for hydrophobic membranes has been set by poly(dimethylsiloxane) a silicone rubber membrane popularly abbreviated as PDMS. This is a room temperature vulcanization (RTV) type rubber. It is generally made from a two-pot mixture consisting of the silicone rubber and a cross-linker. Poly(octyl methyl siloxane), POMS, is a similar silicone rubber. POMS has a higher hydrophobicity than PDMS but is more expensive. Most investigators have used PDMS although some have also used EPDM and other rubbers [16]. PDMS appears to be the optimum membrane polymer for high selectivity, flux, and durability. Table 5.5 gives a summary of the literature investigations on removal/recovery of organics from aqueous solutions.

PV offers an extremely promising technology for treating effluents containing dissolved organics, which is apparent from Figure 5.2. A hydrophobic membrane module is used to recover (almost) completely the dissolved organics from the effluent.

**TABLE 5.5 (continued)**  
**Removal of Organics from Aqueous Solutions**

System	Membrane Used	Remark	Reference
Recovery of aroma compounds from wine-must fermentation	PDMS on polyetherimide	Continuous recovery of very complex and delicate aromatic profiles, produced during microbial fermentation	[115]
Recovery and separation of 1-octene-3-ol from aqueous solution	PDMS membrane	Good selectivity and permeability	[116]
Recovery of aroma compounds (1-octene-3-ol, ethyl acetate/butyrate/hexanoate)	Plain PDMS and PDMS filled with silicalite	Influence of different permeates studied. Filled membrane gives better selectivity than plain PDMS but lower flux	[117]
Recovery of picolines from aqueous solutions	Elastomeric membranes	$\alpha$ as high as 150 reported	[118]
Recovery of aroma compounds	Poly(octyl methyl siloxane) (POMS) and PDMS	The effects of operating conditions on separation performance were studied. POMS membrane was more perm-selective to the aroma compound than PDMS. $\beta$ higher for ETH than for ETB	[119]
Recovery of aroma compounds	Organophilic membranes	Review. Comparison of membrane performance for aroma compounds with different functional groups	[120]
Recovery of apple juice aroma compounds	PDMS	$\beta$ values ranging from 5–10 for ethanol to >100 for esters reported	[121]
Recovery of tea aroma compounds ( <i>trans</i> -hexenal 2-methyl propanal 3-methylbutanal phenyl acetaldehyde benzyl alcohol Linalool <i>cis</i> -3-hexenol-ionone)	Poly(octyl methyl siloxane) and poly(dimethylsiloxane)	Wider range of $\beta$ (20 to 1100) depending upon the functional group. PDMS found to be better than POMS	[20]
Removal of various organic compounds from industrial effluent; recovery of apple aroma	Composite MTR 100	Selectivities vary with the nature of the organic compound ranging from >100 for highly hydrophobic to ~5 for highly hydrophilic compounds	[122]
Scale-up of pervaporation for the recovery of natural aroma compounds in the food industry. Part 2: Optimization and integration	Hydrophobic membranes	Economic analysis of PV shows high potential for aroma recovery	[123]
Scale-up of pervaporation for the recovery of natural aroma compounds in the food industry. Part 1: Simulation and performance	Hydrophobic membranes	Importance of simulation in recovery from multicomponent mixtures revealed	[124]
Pervaporation for aroma isolation	Organophilic membrane	Recent developments in this field and the economic implications of the technology for producing natural aroma extracts are studied	[125]
Aroma compounds recovery of tropical fruit juice by pervaporation	Composite membranes (flat or hollow fiber),	The water permeability and the overall mass transfer coefficient for each organic solute was determined	[126]
<b>Bioproduction</b>			
Ethanol production	Silicone composite on polysulfone	Productivity of 20–30 g/L h	[127]
Acetone, butanol, ethanol fermentation	SBR,EPDM,PDMS plain and filled with silicalite	Highest $\alpha$ obtained for filled PDMS and lowest for EPDM. SBR yielded highest PSI	[87]
Recovery of acetone and butanediol from fermentation broth	PDMS and PEBAX	PEBAX better than PDMS. Fermentation coupled with PV at $\beta > 2$ can eliminate product inhibition	[128]

**TABLE 5.5 (continued)**  
**Removal of Organics from Aqueous Solutions**

System	Membrane Used	Remark	Reference
Recovery of volatile organic flavor compounds (ethyl acetate, EA; ethyl propionate, EP; ethyl butyrate, EB)	Surface modified tube-type alumina membrane	$\beta$ for EA, EP, and EB at 40°C were in the range of 66.9–78.9, 106.5–97.3, and 120.5–122.8, respectively. Phase separation in permeate allows facile recovery of the aroma compounds	[129]
Product recovery from biomass fermentation processes	Hydrophobic/hydrophilic membranes for recovery of biofuel and dehydration, respectively	Several issues and research priorities which will impact the ability of pervaporation to be competitive for biofuel recovery from fermentation systems are identified and discussed	[130]
Ethanol recovery from fermentation broth by pervaporation	Composite polydimethylsiloxane membrane	Ethanol concentration in fermentation broth decreased to a relatively low level when pervaporation was coupled with fermentation. More active cells appeared accompanied by better membrane performance	[131]

The selectivities of a typical organophilic membrane [16,18] are such that the permeate is enriched in terms of the organic well above its solubility limit. At these concentrations phase splitting occurs. In the liquid–liquid separator (Figure 5.3), two separate layers (1) organic rich with minute quantity of dissolved water and (2) water rich but saturated with the organics are obtained. The second small stream containing water saturated with the organics is returned to the feed side of the module. Figure 5.3 shows a closed loop operation with only the untreated (mainly aqueous) stream going to the effluent treatment plant. An idea of importance of the process shown in Figure 5.3 can be obtained from the following example. Although benzene has a low solubility (~1000 ppm) in water each mole of benzene requires 7.5 moles of oxygen for complete conversion to CO<sub>2</sub> and H<sub>2</sub>O. Removal of more than 90% of the benzene is possible by employing the process in Figure 5.3. This implies a significant decrease in the chemical oxygen demand (COD) load on the effluent treatment plant. At the same time the recovered organic is an added value to the organization.

Another very important application of PV in this class is recovery of high value aroma compounds. Baudot and Marin [85] have presented an excellent review on recovery of aroma compounds by PV. A comparison with recovery by stripping is also made. A recent paper [20] covers the subsequent literature. From the available literature, it is clear that PV is a far better option than stripping for aroma recovery. The major advantages of PV are (1) high selectivities and (2) mild operating conditions, which prevent the thermal degradation of the relatively sensitive aroma compounds. However, as pointed out by Kanani et al. [20] the sensory profile of the recovered aroma mixture can be significantly different because of the different selectivities offered by the membrane for the various aroma compounds present in the original mixture. In their study on recovery of tea aroma compounds by PV the following observations were made.

**FIGURE 5.3** Schematic of recovery of dissolved organics using pervaporation.

Generally, alcohols showed higher separation factors when present in model multicomponent solutions than in binary systems with water. On the other hand, aldehydes showed an opposite trend. The actual tea aroma mixture showed a rather different behavior from the model aroma mixture, probably because of the presence of very large numbers of unknown compounds. Overall, the PDMS membrane with vinyl end groups used by Kanani et al. [20] showed higher separation factors and fluxes for most of the aroma compounds. Pervaporation was found to be an attractive technology. However, as mentioned above the varying selectivities for the different aroma compounds alter the sensory profile and therefore application of PV for recovery of such mixtures needs careful consideration on a case-by-case basis.

PV has another potential application in the biotechnology industry, which may expand rapidly [86]. There is a clearly perceptible trend of use of biotechnology for the manufacture of specialty flavor materials. The product of the process inhibits most fermentation. If this product is continuously removed from the broth much higher productivities can be obtained. Liquid extraction, which was studied in the 1960s and 1970s, for removal of the fermentation products has the drawback that the solvent used may be toxic to the microorganisms. Inert gas stripping/vacuum stripping offer much lower separation factors. In view of the capability of PV to efficiently separate organic compounds under mild conditions, it is a far better substitute to these competing methods particularly if the product is volatile enough to be amenable to removal by PV. Kawedia et al. [87] have studied the pervaporative removal of the products in acetone–butanol–ethanol (ABE) fermentation using various organophilic membranes. These investigators studied both binary (organic–water) and quaternary (A/B/E/H<sub>2</sub>O) systems. In this fermentation butanol has the most detrimental effect on the activity of the microorganisms. Amongst the various polymers studied styrene butadiene rubber was found to be best for removal of the toxic products from the quaternary mixture. Similar applications in the manufacture of other aroma/flavor compounds such as *cis*-3-hexenol (leaf alcohol), pyrazines, etc. need urgent attention. Table 5.5 lists the available literature investigations on removal of organics from predominantly aqueous systems.

### 5.4.3 ORGANIC–ORGANIC SEPARATIONS

In the applications of PV discussed in Sections 5.5.1 and 5.5.2, there are clear and substantial differences in the properties of the solutes to be separated. The major distinguishing features relate to the polarity/hydrogen bonding properties of the solutes. Thus, the selection of the membrane polymer is relatively easy. In the case of organic–organic systems only in the case when one of the solutes contains strong hydrogen bonding (OH) or polar groups while the other is entirely nonpolar, the selection of the polymer can be done by the thumb rule of hydrophilicity/hydrophobicity of the polymer. Examples of such systems are: methanol–toluene, methanol–benzene, *i*-propanol–toluene/benzene, etc. [25–28]. On the other hand, when both the solutes have similar properties the selection of the membrane polymer requires careful consideration. However, in this case also small differences in the polarity of the solutes can be exploited to effect relatively good separation. Ray et al. [23,24] developed several methanol-selective copolymer membranes for separating methanol from MTBE and ethylene glycol. These investigators used the concept of three-dimensional (3-D) solubility parameter and prepared several copolymers of AN with other hydrophilic monomers like HEMA, vinyl pyrrolidone, etc. By properly tuning the copolymer composition membranes with relatively high selectivities for methanol were obtained. These membranes have good stability because the hydrophilic group, which is bonded to the AN backbone, is not easily plasticized by methanol. Similar approach was successfully applied by Ray et al. [22] to effect the much more difficult separation of benzene and cyclohexane. These two compounds have substantially the same properties except that due to the continuous shifting of the double bonds in benzene there is a small contribution from polar and hydrogen bonding forces to the overall solubility parameter of benzene. In this case copolymers of AN with relatively hydrophobic compounds like methyl methacrylate, vinyl acetate, and styrene were employed for obtaining benzene-selective membranes. The choice of the comonomers was dictated by the fact that their homopolymers are soluble in benzene and thus their inclusion in the copolymers would enhance benzene sorption. The extent of the comonomer in the copolymer was varied to obtain an optimum composition. All the membranes were found to yield benzene selectivities much higher than those reported earlier. The selectivities depended upon the copolymer type and its composition, and varied from 5 to 80. This work clearly proves the utility of the copolymer concept combined with the 3-D solubility parameter theory to design suitable membranes for relatively difficult separations. Further, because of the presence of the relatively tough and insoluble AN backbone these membranes are very stable.

Table 5.6 gives a summary of the literature investigations on organic–organic separations. The early enthusiasm for PV was a result of its various advantages vis-à-vis distillation. This was evident from the fact that most majors like Exxon, Standard Oil, British Petroleum, Texaco established research groups devoted to PV. The group at Exxon made a concerted effort at developing membranes for separating close boiling aromatic/aliphatic compounds. However, the selectivities obtained with the optimized membranes were still not good enough to encourage a change over from distillation. Indeed, these rather unsuccessful efforts eventually resulted in closure of many groups. Currently, only a small number of companies (Sulzer Chemtech, Ube and Mitsui, Japan and MTR, USA) are active in this area. Thus, despite the advantages of PV and its potential applicability to a wide range of organic–organic separations of great industrial interest, there are very few known actual examples of industrial use. Steinhauser et al. [132] have described the separation of an azeotropic mixture of trimethyl borate

**TABLE 5.6**  
**Organic–Organic Separation**

System	Membrane Used	Remark	Reference
Butadiene is separated from its mixture with <i>trans</i> -2-butene	Polybenzimidazole membrane	$\beta = 4.9$	[134]
1,3-butadiene is separated from its mixture with <i>trans</i> -2-butene	PVC membrane	Separation of dienes from mono-olefins	[135]
Removal of methanol from organic mixture	Membrane prepared by plasma polymerization	High $\alpha$ and flux for methanol reported	[136]
Separation of organic–organic mixture	Various organic and inorganic membranes	Review on current scientific and technological factors governing separation of organic mixtures	[137]
Toluene/heptane	Polyacrylonitrile composite membrane	High selectivity and high permeate fluxes were obtained	[138]
Separation of MeOH-hydrocarbon and EtOH-ETBE mixtures	Plasma polymerized PERVAP 1137	High methanol/MTBE and ethanol/ETBE selectivities. PV + distillation more economical	[139]
Separation of alcohol toluene mixture	<i>N</i> -acetylated chitosan membrane	Additional acetyl groups in the membrane decreased the flux but increased $\alpha$	[140]
<i>N</i> -butyl acetate- <i>n</i> -butanol-methyl acetate-methanol	Sulzer Pervap-2255 membrane	Combination of reactive distillation and pervaporation allowed 100% conversion	[141]
Pervaporation of methanol-methyl acetate binary mixtures	Cuprophane membranes	Experimental fluxes and selectivities of the permeating components were determined and evaluated on the basis of the feed mixtures and membranes. The effect of vacuum/pressure on total flux and selectivity is discussed	[142]
Separation of organic–organic mixture	Hydrophilic polymer membrane	Review: Mass transfer analysis of pervaporation	[80]
MeOH-cyclohexane, EtOH-cyclohexane, Me-pentane, and MeOH-MTBE	Membrane from a 5% NA cellulose sulfate solution and 20%–40% solutions of cationic surfactants e.g., <i>N</i> -dodecylpyridinium chloride or hexadecylpyridinium chloride	In all cases high fluxes and good selectivities at 50°C were found	[143]
Separation of azeotropic mixtures like water, MeOH, and EtOH from organic solvents	Hybrid PV + distillation systems	Applications and flow sheets for hybrid processes	[144]
Separation of azeotropic organic liquid mixtures	PFSA polymer composite membrane	The composite membrane gave 4–5 times larger flux than commercial membrane without appreciable loss in selectivity. Downstream pressure of ~6.67 KPa had little effect on the total flux	[145]
Methanol-benzene and methanol-toluene	Regenerated cellulose (cellophane), poly(vinyl alcohol) (PVA), cellulose acetate (CA), cellulose triacetate (CTA), two blends of CTA (B1 and B2) with acrylic acid, poly(dimethylsiloxane) (PDMS), and linear low density polyethylene (LLDPE) membrane	Methanol selectivity PVA > CA > CTA > B1 > B2. The influence of the membrane material with varying solubility parameter is investigated	[24]
1-Methoxy propanol and water	Polyimide (PI), cellophane, poly(vinyl alcohol) (PVA), cellulose diacetate (CDA), cellulose triacetate, two separate blends of cellulose acetate and CDA with cellulose acetate propionate, and PVA cross-linked with multifunctional cross-linkers	The effects of different substitution derivatives of cellulosic materials were investigated	[74]
1-Methoxy propanol and water	Acrylonitrile-based copolymer membrane	3-D solubility parameter and interaction parameter values used to explain behavior (selectivity and flux). Copolymers of AN showed good selectivity with reasonable flux	[15]

(continued)

**TABLE 5.6 (continued)**  
**Organic–Organic Separation**

System	Membrane Used	Remark	Reference
IPA/benzene, IPA/toluene	Regenerated cellulose (cellophane), poly(vinyl alcohol) (PVA), cellulose acetate (CA), cellulose triacetate (CTA), two blends of CTA (B1 and B2) with acrylic acid, poly(dimethylsiloxane) (PDMS), and linear low density polyethylene (LLDPE) membrane	The IPA selectivity performance was: cellophane > PVA > CA > CDA > CTA	[26]
Methanol-toluene	Acrylonitrile-based copolymer membrane	The permeation, selectivity, and flux variation with methanol concentration has been explained using the solubility parameter approach	[15]
Benzene and cyclohexane mixtures	Copolymers of acrylonitrile with styrene, methyl methacrylate, and vinyl acetate	Copolymers of acrylonitrile with methyl methacrylate and vinyl acetate showed good selectivity and moderate flux	[146]
Methanol removal from mixtures with toluene, MTBE, IPA, and acetonitrile	Polypyrrole membrane doped with hexafluorophosphate (I) and p-toluenesulfonate (II)	Membrane (I) gave high selectivity and acceptable flux	[147]
Separation of organic liquid mixtures	Liquid crystalline polymer networks	Change in selectivity from H <sub>2</sub> O selective to ethanol selective at the nematic-isotropic transition temperature	[148]
Separation of the benzene/cyclohexane mixtures	Poly(methyl methacrylate) (PMMA) and poly(ethyl methacrylate) (PEMA) cross-linked with ethylene glycol dimethacrylate (EGDM)	The depression of swelling of membranes with the increase of the cross-linker content in the benzene/cyclohexane mixtures enhanced benzene permselectivity	[149]

### Special Applications

Separation of liquid mixture	Application of PV and VP	General review, examples of polymers for membrane preparation, as well as performance parameters of pervaporation and vapor permeation membranes, are described	[159]
Esterification/alkylation, deNO <sub>x</sub> reaction, hydrogenation, and dehydrogenation studied	Zeolite molecular sieve membrane	It is found that zeolite membranes, disk, and coating show high performance or potential as catalysts compared with conventional catalysts	[160]

and methanol using vapor permeation unit. VP is the analog of PV wherein the feed is vapor instead of liquid. Another documented application is in the manufacture of MTBE and ETBE. Both these ethers form an azeotrope with the alcohol. In a detailed engineering study Hommerich [133] has shown that PV can be advantageously used in a large-scale plant with significant savings in operating costs.

With the rising cost of crude oil and hence that of fuel, distillation may be placed at a greater disadvantage because of its energy intensive nature. PV, with its low-operating costs is most likely to receive a revived interest. Particularly important applications of interest will be separation of organic azeotropes and close boiling mixtures. A concerted effort is needed to develop membranes with higher selectivities than the currently available one to ensure that PV does not remain a small-scale application [59].

## NOMENCLATURE

$a_i$	activity of component $i$
$A_{ii}, A_{ij}, A_{jj}, A_{ji}, B_{ij}, B_{ji}$	diffusional interaction parameters in Section 5.2
$A_i$	plasticization coefficient ( $\text{m}^3/\text{mol}$ ) <sup><math>n</math></sup> in Equations 5.15 and 5.17
$C_3(r, \phi)$	molar concentration at the pore outlet ( $\text{mol}/\text{m}^3$ )
$C_3(r, z)$	molar concentration in the cylindrical pore at a point ( $\text{mol}/\text{m}^3$ )
$C_{bi}$	concentration of component $i$ in the bulk in Equation 5.6 ( $\text{mol}/\text{m}^3$ )
$C_{fi}$	concentration of selectively permeating solute $i$ in the feed in Equation 5.28 ( $\text{mol}/\text{m}^3$ )
$C_{pi}$	membrane phase concentration of 'i' in the permeate side in Equation 5.28 ( $\text{mol}/\text{m}^3$ )
$C_{mi}$	concentration of a component $i$ in the membrane in Equation 5.6 ( $\text{mol}/\text{m}^3$ )
$C_m$	membrane phase concentration of the solute in Equations 5.7 and 5.8 (wt. fraction)
$C_b$	bulk liquid phase concentration of the solute in Equation 5.8 (wt. fraction)
$C_T$	total concentration of the solute in the membrane in Equation 5.7 ( $\text{mol}/\text{m}^3$ ) (wt. fraction)
$C_z$	weight fraction of solute in zeolite phase
$D$	diffusion coefficient ( $\text{m}^2/\text{s}$ )
$D_i$	diffusion coefficient of component $i$ ( $\text{m}^2/\text{s}$ )
$D_{io}$	diffusion coefficient of component $i$ at infinite dilution ( $\text{m}^2/\text{s}$ )
$D_{jo}$	diffusion coefficient of component $j$ at infinite dilution ( $\text{m}^2/\text{s}$ )
$d_{\text{pore}}$	pore diameter (m)
$\Delta H_f$	heat of fusion of polymer in Equation 5.13 (kJ/kmol)
$H_M$	Henry's constant in Equation 5.8 (—)
$J_i$	flux of component $i$ ( $\text{kg}/\text{m}^2\text{s}$ ) ( $\text{mol}/\text{m}^2\text{s}$ )
$K$	sorption coefficient for the solute in the polymer in Equation 5.6 (—)
$k_o$	overall mass transfer ( $\text{m}/\text{s}$ )
$K_o$	overall mass transfer coefficient in Equation 5.29 ( $\text{m}/\text{s}$ )
$k_L$	fluid to membrane mass transfer coefficient in Equation 5.29 ( $\text{m}/\text{s}$ )
$k_{di}, k_{dj}$	constants in Equations 5.18 through 5.21
$L$	thickness of membrane in Equation 5.28
$M_c$	molecular weight between two cross-links
$M_V$	molecular weight of repeating unit of polymer ( $\text{kg}/\text{mol}$ )
$n$	constant in Equation 5.15

$n_1, n_2$	number of moles of component 1 and 2, respectively, in Equation 5.4
$n_i$	ratio of molar volume of polymer to solute in Section 5.2
$P_i^C$	critical (partial) vapor pressure of component $i$ in Equation 5.35
$P_i^o$	partial pressure of component $i$ at equilibrium state in Equation 5.35
$p_2$	effective pressure (atmospheric pressure/RO pressure) of A and B at the pore inlet in Equation 5.1 (—)
$p_3$	effective pressure (atmospheric pressure/RO pressure) of A and B at the pore outlet in Equation 5.1 (—)
$R, z$	cylindrical coordinates (m)
$R$	universal gas constant (8.314 kJ/kmol K)
$S$	sorption coefficient in Equation 5.29 (—)
$S_A$	sorption coefficient for A (—)
$S_B$	sorption coefficient for B
$T$	temperature (K)
$T_m$	melting temperature of the crystalline phase (K)
$U$	solution velocity in pore (m/s)
$V_i$	molar volume of component $i$ (cm <sup>3</sup> /mol)
$V_1, V_2$	molar volumes of components 1 and 2, respectively, in equations in Section 5.2 (m <sup>3</sup> /mol)

### GREEK LETTERS

$\alpha_S$	sorption selectivity (—)
$\alpha_D$	diffusional selectivity (—)
$\alpha_o$	overall selectivity (—)
$\beta$	separation factor defined by Equation 5.33 (—)
$\chi_{AB}, \chi_{AM}$	friction constants between A
$\chi_{ip}$	interaction parameter for component $i$ (—)
$\delta$	overall solubility parameter (MPa) <sup>1/2</sup>
$\delta_p$	length of the pore (m) in Equation 5.1
$\delta_d$	contribution of dispersive force toward solubility parameter (MPa) <sup>1/2</sup>
$\delta_h$	contribution of hydrogen bonding toward solubility parameter (MPa) <sup>1/2</sup>
$\delta_p$	contribution of polar forces toward solubility parameter (MPa) <sup>1/2</sup>
$\Phi_p$	volume fraction of the polymer (—)
$\eta$	solution viscosity in the pore (Pa s)
$\lambda$	fraction of noncrystalline polymer in Equation 5.13 (—)
$\Delta\mu$	chemical potential difference between the two phases in Equation 5.10
$\rho_p$	polymer density (kg/m <sup>3</sup> )
$\sigma_p$	surface tension of liquid in pore (N/m) in Equation 5.35

### ABBREVIATIONS

A	solute, A
ABE	acetone–butanol–ethanol
AN	acrylonitrile
B	solute, B
CA	cellulose acetate
CDA	cellulose diacetate
COD	chemical oxygen demand
CP	concentration polarization
CPI	chemical process industries
CTA	cellulose triacetate
EA	ethyl acetate
EB	ethyl butyrate
EGDM	ethylene glycol dimethacrylate
EP	ethyl propionate
EPDM	ethylene propylene diene
ETBE	ethyl <i>tert</i> -butyl ether
FTSM	facilitated transport supported liquid membrane

HEMA	hydroxyethyl methacrylate
IPN	interpenetrating polymer networks
LDPE	low density polyethylene
MARS	membrane aromatic recovery system
MF	microfiltration
MMA	methyl methacrylate
MS	mild steel
MTBE	methyl <i>tert</i> -butyl ether
NBR	<i>N</i> -butyl rubber
NR	natural rubber
NRS	nonrenewable resources
PAA	poly(acrylic acid)
PCE	perchloroethylene
PDMS	poly(dimethylsiloxane)
PEBA	poly(etherimide block polymer)
PEMA	poly(ethyl methacrylate)
PFSA	perfluoro sulfonic acid
PMMA	poly(methyl methacrylate)
POMS	poly(octyl methyl siloxane)
PP	poly(propylene)
PSCF	preferential sorption–capillary flow
PSI	pervaporation separation index
PV	pervaporation
PVA	poly(vinyl alcohol)
PVC	poly(vinyl chloride)
RO	reverse osmosis
RTV	room temperature vulcanization
SBR	styrene butadiene rubber
Δ	signifies difference in two properties

## ACKNOWLEDGMENT

VGP wishes to gratefully acknowledge the Herculean efforts of Mr. Rajendra Prasad and Ms. C. Sona in editing the manuscript as per CRC format.

## 6.1 INTRODUCTION

Ceramic membranes offer significant advantages of polymeric membranes in many applications where the last ones cannot withstand operating conditions (pH, temperature, chemicals, etc.). Indeed polymeric membranes are still cheaper to produce than ceramic membranes and are commercially available in a large range of polymeric materials and module geometry. Nevertheless, a technical and economical comparison between different membrane processes must take into account both investment and maintenance costs. Investment involves the cost of equipments for pretreatment and posttreatment of fluids in addition to the cost of the membrane plant. Maintenance includes replacement of membranes, electricity consumption, cleaning products, and labor costs. Accordingly, a comparison of overall costs, including membrane lifetime, cleaning procedures, and pretreatment requirements, may be in favor of inorganic membranes in a number of applications. Moreover, the technical progress made in the fabrication of ceramic membranes with production costs getting closer to those of many polymeric membranes explains why they are entering markets much broader than those accessible to the first generation of ceramic membranes.

Porous ceramic membranes are now widely applied in microfiltration and ultrafiltration, and they are getting to enter the nanofiltration domain. In fact, the structure of ceramic membranes readily changed since their first development. Membrane elements have gained higher compaction and are now produced with pore sizes down to the microporous range referring to IUPAC classification. Actual ceramic membrane elements are composed of a macroporous inorganic material (with a flat, tubular, multichannel, or monolithic geometry) supporting a multilayer porous ceramic structure exhibiting a non-deformable porosity with pore sizes ranging from macropores to micropores. Ceramic membrane elements are the basic units in which mass transfer and separation obey different transport mechanisms relating first to membrane physical characteristics (pore size, porosity, and membrane thickness), then to physicochemical interactions between feed liquid and membrane surfaces, and finally to hydrodynamics in the element. Most often, commercial ceramic membrane modules are made of a stainless steel housing containing one or several membrane elements. Beyond the current porous ceramic membranes devoted to liquid filtration, new generations of microporous or dense ceramic membranes are likely to develop for gas and vapor separation or biological and chemical catalytic reactors. In particular, much attention has been paid recently to dense ceramic membranes exhibiting high oxygen or hydrogen separation selectivity in view of applications in new technologies for power generation. Transport mechanisms in these dense ceramic membranes are based on ion conduction in the solid at high temperature.

This chapter is divided in three main parts. A current status of ceramic membrane technology is presented in the first part dealing with the description of commercially available ceramic membrane elements and modules as well as a brief overview of basic transport and separation mechanisms of these membranes. The second part looks through the current applications of ceramic membranes that have been classified into three domains: treatment of wastes, processing of liquids, and recovery of products. The third and last part of this chapter presents recent developments and prospects in the segment of ceramic membrane technologies. Part of these new developments anticipate the emergence of new ceramic membranes exhibiting a higher selectivity and able to withstand much severe working conditions than currently available ceramic membranes.

## 6.2 CERAMIC MEMBRANE TECHNOLOGIES

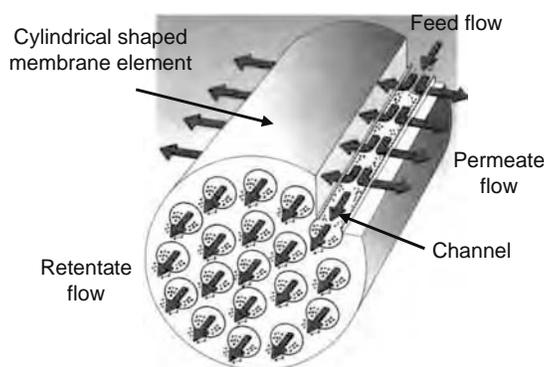

### 6.2.1 DESCRIPTION OF CERAMIC MEMBRANES

Currently available ceramic membranes are generally made up of a macroporous support, one or several macroporous intermediate layers, and a meso- or microporous top-layer. A comprehensive description of ceramic membrane top-layers can be found in a number of papers, reviews, and books [1–7]. In these publications, data are mainly devoted to the membrane top-layer, but less information is available on ceramic membrane elements. These elements may differ in structural shape and in chemical composition. The production of membrane elements combines the utilization of processing technologies such as ceramic paste extrusion for supports, slip-casting of powder suspensions for microfiltration layers [2], or solgel processing [8] of colloidal suspensions for ultra- or nanofiltration layers. The latest developments of ceramic membranes also include dense ion-conducting materials used for gas separation at high temperature. At the commercial level, ceramic membranes are available as modules made up of a rigid casing that contains one or several membrane elements.

#### 6.2.1.1 Membrane Elements

Although some ceramic membrane elements are proposed with a flat geometry, most of them exhibit a cylindrical shape for a multichannel element (Figure 6.1). The reason for that is the much better mechanical properties obtained for cylindrical-shaped ceramics and the easier sealing of the elements compared to flat shapes.

Since their early development, the geometrical and structural characteristics of ceramic membrane elements have readily changed (Figure 6.2). Originally, they were prepared as single tubes with an inside diameter ranging from ~6 to 15 mm and a wall thickness of about 2 mm. These ceramic tubes are still available from some suppliers, but the main handicaps with such

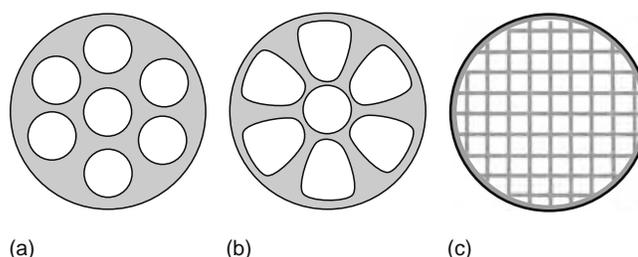

**FIGURE 6.1** Schematic representation of the multichannel structure of a ceramic membrane element.

tubular geometry are the high element volume to membrane surface ratio and the high liquid flow required for module feeding. The problem was solved rapidly by developing multichannel geometries as shown in Figure 6.2a. Actually, channels of a few millimeters in diameter minimize both the volume to membrane surface ratio and the feed flow inside the modules. Later on, the volume to membrane surface ratio was still increased by changing the cylindrical shape of the channels for non-cylindrical flower-like geometries, optimizing both space occupancy of the membrane and channel wall thickness in the element (Figure 6.2b). Recently, monolithic structures (Figure 6.2c) with a high density of cells and thin walls led to much larger hydraulic section and high membrane surface per element. Such an evolution of element geometry has resulted in a significant improvement of the filtration capability of ceramic membranes. All these ceramic membrane elements are currently available on the market. A number of relevant examples showing the evolution of these products are discussed hereafter [9].

Originally, multichannel ceramic membranes have been produced at the industrial scale by SCT-Exekia and Orelis in France with commercial elements registered, respectively, as Membralox and Kerasep. The membrane filtration area in this case can reach  $0.35 \text{ m}^2/\text{element}$  depending on channel diameter and the number of channels per element. FILTANIUM elements, representative of flower-like geometries, have been produced more recently by TAMI industries in France (Figure 6.3). These elements with a cross-section diameter of either 10 or 25 mm exhibit a number of channels that vary from 3 to 39 and a membrane filtration area of  $0.5 \text{ m}^2$  for the largest elements. The increase in membrane surface compared to equivalent cylindrical-shaped channels can be estimated at 30%.

The more recent monolithic structure (Figure 6.2c) results in a significant increase in surface to element volume ratio compared to the previous geometries. A typical monolith membrane element has multiple square-shaped parallel passage ways separated by porous walls through which permeate is drained at the exterior of the element. The tight arrangement of cells with a small cross-section area generates an efficient turbulent flow in the channels, a reduced pumping energy for feed flow, and a high filtration surface per element. Manufacturing of these large monoliths, up to 200 mm in diameter and 1.50 m long, has been successfully achieved by a number of companies mentioned in Table 6.1. The image of such full-size  $10.7 \text{ m}^2$  membrane element from CeraMem (Waltham, Massachusetts) is displayed in Figure 6.4.

However, there is a limitation in increasing the diameter of monolith membrane elements. The upper limit is when the hydraulic resistance of the porous walls becomes higher than the hydraulic resistance of the membrane top-layer developing in the element. A solution to this problem was found by introducing permeate conduits within the monolith. An example of such monolith design, patented by CeraMem, is given in Figure 6.5. Permeate conduits are obtained by cutting slots on both ends of the monolith, and sealing the ends of these slots. Then the cells at the opposite end of the monolith, opening into the slots are sealed. After sealing the slots/cell opening at both ends of the monolith, it is coated with membrane.

**FIGURE 6.2** Evolution of the geometry of ceramic membrane elements. (a) Conventional cylindrical-shaped channels; (b) flower-like designed channels; and (c) honeycomb-type structure.

**FIGURE 6.3** Ceramic membrane elements with a flower-like geometry, from TAMI industries.

Hollow fiber (outer diameter  $<0.5$  mm) and capillary (outer diameter  $>0.5$  mm) ceramic membranes constitute the very last development in the field of inorganic membranes. As for polymer hollow fiber membranes, a large surface/volume ratio is expected for the modules as well as the possibility of keeping uppermost properties of ceramics, i.e., high mechanical, chemical, and temperature resistance. Interestingly, ceramic hollow fibers or capillaries with an asymmetric structure (Figure 6.6a) have been obtained in single-stage process and used as support for coating of microporous membrane top-layers [10]. CEPARation, newcomer on the ceramic membrane market, has developed compact and low-cost ceramic filters based on hollow fiber and capillary ceramic membranes. The modules ranging from  $0.05$  to  $1$  m<sup>2</sup> are claimed to be suitable for micro-, ultra-, and nanofiltration. Certain modules can be specially designed for gas separation and high-temperature applications up to  $700^{\circ}\text{C}$ . Polymeric resin or ceramic potted inserts of such ceramic hollow fibers or capillaries, suitable for plastic or stainless steel housing, are shown in Figure 6.6b and 6.6c.

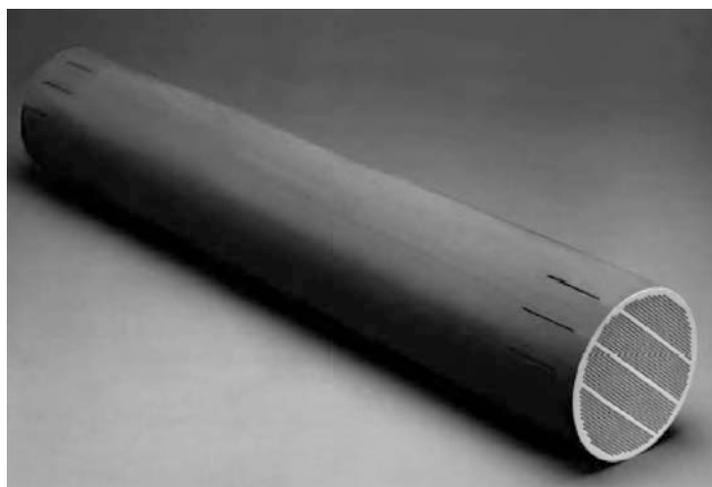

### 6.2.1.2 Porous Membrane Structure

Homogeneous ceramic porous structures with pore diameter larger than  $1$   $\mu\text{m}$  can be used directly for microfiltration, however, most of ceramic membrane elements are constructed from supported multiple ceramic layers constituting an asymmetric porous structure. Scanning electronic microscopy (SEM) images are shown in Figure 6.7 of asymmetric or homogeneous porous structures encountered in glass, carbon, or ceramic membrane materials. The most common ceramic materials used for ceramic membranes and support fabrication have been alumina, titania, and zirconia. Cordierite, silicon carbide, and silicon nitride have been used more recently, in particular for membrane monoliths. Glass as a homogeneous porous material may also be included in the category of available inorganic membrane materials. To a less extent, metallic or carbon macroporous materials may be mentioned as other types of support elements used for ceramic membrane deposition.

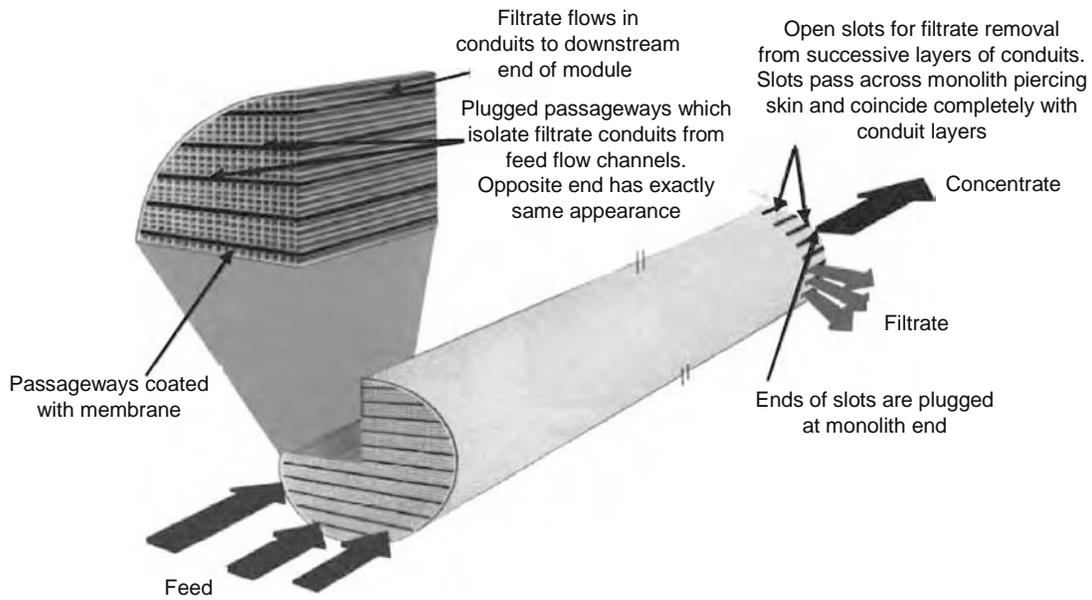

The porous structure of ceramic supports and membranes can be first described using the IUPAC classification on porous materials. Thus, macroporous ceramic membranes (pore diameter  $>50$  nm) deposited on ceramic, carbon, or metallic porous supports are used for cross-flow microfiltration. These membranes are obtained by two successive ceramic processing techniques: extrusion of ceramic pastes to produce cylindrical-shaped macroporous supports and slip-casting of ceramic powder slurries to obtain the supported microfiltration layer [2]. For ultrafiltration membranes, an additional mesoporous ceramic layer ( $2$  nm  $<$  pore diameter  $<50$  nm) is deposited, most often by the solgel process [11]. Ceramic nanofilters are produced in the same way by depositing a very thin microporous membrane (pore diameter  $<2$  nm) on the ultrafiltration layer [4]. Two categories of micropores are distinguished: the supermicropores  $>0.7$  nm and the ultramicropores  $<0.7$  nm.

**TABLE 6.1**  
**Characteristics of Inorganic Membrane Products Currently Available on the Market**

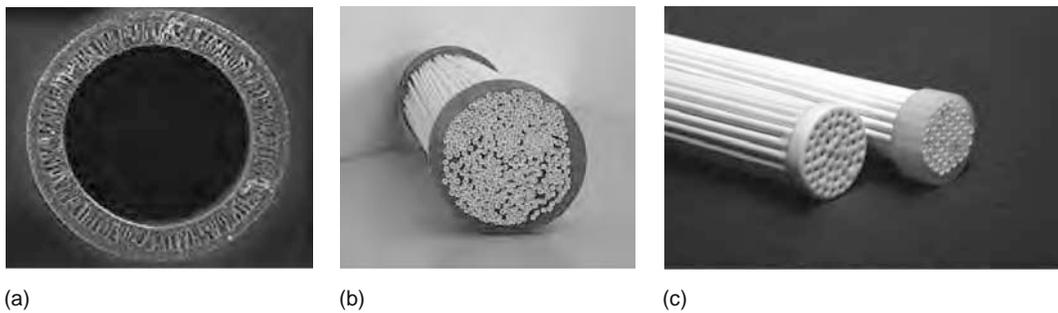

Manufacturer	Trade Name	Membrane Material	Pore Size	Shape
Asahi Glass		Glass	0.1–1.4 $\mu\text{m}$	Tube
Atech		SiC/SiC	0.05–1.0 $\mu\text{m}$	Tube
		$\text{Al}_2\text{O}_3$		Multichannel
Bekaert		SS fiber media	Macroporous	Tube
CEPARation		$\text{Al}_2\text{O}_3$	0.3–40 nm	Hollow fiber
CeraMem		Cordierite/SiC		Monolith
CERASIV		$\text{Al}_2\text{O}_3$ , $\text{TiO}_2$ , $\text{ZrO}_2$	5 nm to 1.4 $\mu\text{m}$	Tube
				Multichannel
ECO Ceramics	Sephi-Matic	$\text{Al}_2\text{O}_3$	6 nm to 0.2 $\mu\text{m}$	Tube, disc
Fairey		$\text{Al}_2\text{O}_3$	0.2–0.35 $\mu\text{m}$	Multichannel
Fuji Filters		Glass	4–90 nm	Tube
LiqTech	CrystaMem	SiC	0.5–0.5 $\mu\text{m}$	Monolith
MAST Carbon	Novacarb	Carbon	4–20 $\mu\text{m}$	Tube
			Microporous	Multichannel
				Monolith
Mitsui		Zeolite	Ultramicropous	Tube
				Multichannel
NGK		$\text{Al}_2\text{O}_3$	Macroporous	Monolith
NOK		$\text{Al}_2\text{O}_3$	0.2–6 $\mu\text{m}$	Tube
Pall Exekia	MEMBRALOX	$\text{Al}_2\text{O}_3/\text{ZrO}_2$	20–100 nm	Multichannel
		$\text{Al}_2\text{O}_3/\text{Al}_2\text{O}_3$	0.1–5 $\mu\text{m}$	
Pall	PMF	SS fiber media	Macroporous	Pleatable media
	AccuSep	$\text{TiO}_2$ , $\text{ZrO}_2$ , Ag	1–300 kDa	Disk
Novasep Orelis	CARBOSEP	Carbon/ $\text{ZrO}_2$	1.5 kDa to 0.14 $\mu\text{m}$	Tube
	KERASEP	$\text{Al}_2\text{O}_3/\text{TiO}_2/\text{ZrO}_2$	0.5 kDa to 0.8 $\mu\text{m}$	Multichannel
Sterlitech		ATZ	0.14–14 $\mu\text{m}$	Disk
		$\text{TiO}_2$ , $\text{ZrO}_2$ , Ag	1–300 kDa	
			0.2–5 $\mu\text{m}$	
Sulzer		$\text{SiO}_2$	Micropous	Tube
		Zeolite	Ultramicropous	Multichannel
Sumitomo	Poreceram	$\text{Si}_3\text{N}_4$	50–200 nm	Monolith
Synkera Tech		$\text{Al}_2\text{O}_3$ (anodic)	18–80 nm	Disk
TAMI	FILTANIUM	$\text{TiO}_2$	0.14–1.4 $\mu\text{m}$	Tube
			1–300 kDa	Multichannel
Whatman	ANOPORE	$\text{Al}_2\text{O}_3$	20 nm to 0.2 $\mu\text{m}$	Disk

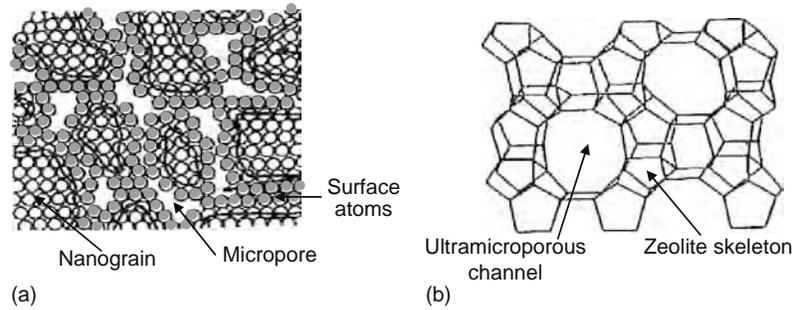

**FIGURE 6.8** Geometry of pores resulting from different particle shapes and processing methods. (a) Bottleneck pore shape; (b) slit pore shape; and (c) ordered porosity.

Ultrafiltration with ceramic membranes is based on mesoporous top-layers. Mesoporosity usually results from residual spaces created between ceramic particles during sintering. Pore sizes are determined by particle size and sintering procedure, while pore geometry depends on particle shape or template effect. A bottleneck geometry (Figure 6.8a) is representative of pores resulting from sintering of almost spherical particles, for example, this is the case of porous structures obtained with titania, zirconia, or  $\alpha$ -alumina particles. When membrane top-layers are produced from platelets suspensions, like clays or  $\gamma$ -alumina particles, slit pore shapes are obtained (Figure 6.8b). More recently, defined pore geometry and regular porous structures have been formed by templates in solgel templated processing methods [12,13]. For example, a cylindrical pore shape may be obtained with lyotropic liquid crystal phases or block copolymer templates (Figure 6.8c).

Presently, plenty of works on microporous inorganic membrane materials are intended to the development of nanofiltration, gas and vapor separation membranes [7]. Two categories of pores are distinguished in microporous inorganic membranes, those resulting from the arrangement and sintering of ceramic oxide nanoparticles and those created during the formation of the intrinsic structure of materials. The ceramic oxide nanoparticles are typically obtained by the solgel process from colloidal suspensions in which particle sizes do not exceed 10 nm [4] or by CVD infiltration techniques [14,15] (Figure 6.9a). One specific feature of these nanograined microporous structures is the presence of a large proportion of surface atoms, 30%–60% for individual grains smaller than 10 nm. Such elevated proportion of surface atoms in the microporous structure of ceramic nanofilters will have a strong influence on mass transport. The second category of micropores is an integral part of the structure of membrane materials such as in zeolite [16] (Figure 6.9b), or carbon materials [17]. For zeolite membranes, top layers are prepared by growth and interpenetration of zeolite crystals under hydrothermal conditions. These layers are supported on/in macroporous ceramic or metal elements. In carbon membranes, the microporous top-layer is generally obtained from graphitization at high temperature of an organic resin. These different microporous structures can be divided in two categories of pore: the supermicropores from 2 to 0.7 nm and the ultramicropores for pores <0.7 nm. Due to the very small size of the pores, surface interaction forces in liquid media or surface adsorption phenomena in gas and vapor media will have a strong effect on mass transfer with these membranes.

### 6.2.1.3 Dense Membrane Structure

Mixed ion and electron conducting (MIEC) or purely ion-conducting ceramics are emerging as an important class of dense inorganic membranes with many potential applications, particularly in the petrochemical and energy sectors [18]. Actually, these membranes are investigated as a potentially economical, clean, and efficient means of producing oxygen by separation from air, and in the future may be for producing pure hydrogen and syngas from industrial processed gases. Membrane design for MIEC ceramic membranes has followed a parallel way to the development of solid oxide fuel cells exhibiting a flat or

**FIGURE 6.9** Microporous membrane structures: (a) resulting from packing and sintering of ceramic nanoparticles and (b) ultramicroporous channels in the crystalline structure of a zeolite.

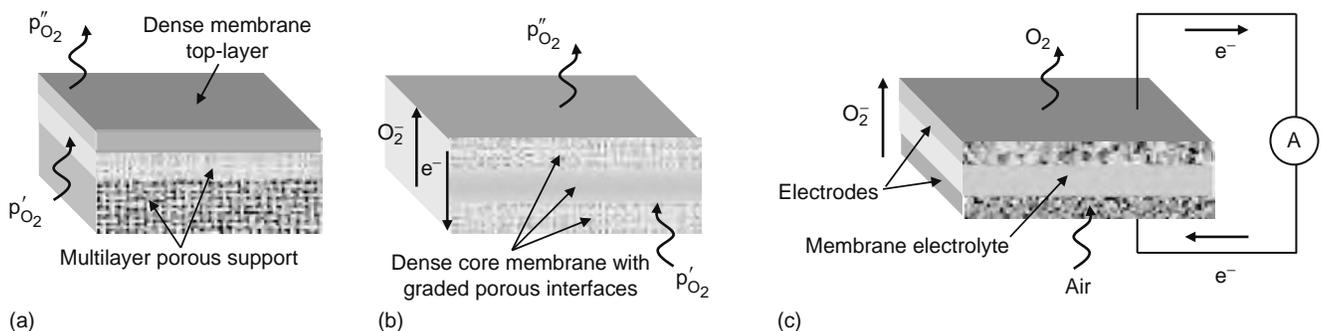

tubular geometry. Up to now these membranes have been studied mainly on the laboratory scale, however, recent achievements in pilot plants development have been mentioned in relation to hydrogen and syngas production. Air Products & Chemicals and partners have produced planar membranes while Praxair showed tubular membranes up to 2 m in length [19]. Tubular membranes have potential advantage of simpler membrane design based on ceramic membranes currently produced for liquid filtration. This could allow faster ceramic fabrication scale-up and development. However, the special microchannel geometry designed by Air Products & Chemicals for planar membranes brings the advantages of superior heat and mass transfer, and higher membrane surface area to system volume ratio leading to more compact system design.

The different membrane concepts currently investigated for selective oxygen transport are shown in Figure 6.10. In the conventional membrane concept, the membrane element consists of a self-supported thick (tubular) material or can be supported as a thin top-layer on a porous support (Figure 6.10a). In advanced designs, the structure of the membrane is made of a dense core material with two porous interfaces made of the same material (mixed ionic–electronic conducting ceramic) in contact with gas phases (Figure 6.10b). The porous interface exhibits a graded porosity and its role is to increase, on one side, the conversion of oxygen molecules from air to ionic species, which are selectively transported in the membrane and converted to oxygen molecules or oxidative species on the other side. A second case is when the two porous interfaces, acting as mixed ionic–electronic conducting electrodes, are made of materials different from the membrane (purely ion-conducting electrolyte), as shown in Figure 6.10c for the oxygen pump application.

### 6.2.2 MASS TRANSFER AND SEPARATION PROPERTIES

This brief overview of mass transfer and separation mechanisms involved in ceramic membrane processes will be useful not only for a better understanding of actual operating conditions of ceramic membranes, but also for anticipating future applications. For example, a same microporous membrane can serve theoretically as liquid or gas separation membrane. However, transport mechanisms and operating conditions being totally different, a good membrane permeability and selectivity in the former case cannot be systematically transposed to the second case.

In liquid filtration using micro-, ultra-, and nanofiltration porous membranes, the driving force for transport is a pressure gradient. Solvent permeability and separation selectivity are the two main factors characterizing membrane performance. Convective flux is predominant with macroporous and mesoporous membrane structures, the selectivity being controlled by a

**FIGURE 6.10** Different membrane concepts for oxygen-ion conducting membranes. (a) Dense mixed conducting membrane top-layer supported on an asymmetric macroporous support; (b) dense self-supported mixed conducting membrane with graded porous interfaces; and (c) solid electrolyte cell (oxygen pump).

sieving effect. In the case of microporous membranes, additional contributions to solute transport and separation must be introduced accounting for diffusive flux and charges exclusion when the solutes and the membrane are carrying electrical charges. Basically, the intrinsic membrane characteristics (pore size, porous volume, thickness, etc.) and operating conditions (transmembrane pressure, cross-flow velocity, concentration polarization, etc.) are the as many parameters influencing permeability and selectivity. Moreover, when real fluids are processed, fouling phenomena due to the accumulation of filtered matter on/in the membrane results in an additional resistance to permeate flux and even in a modification of selectivity. Fouling is a reversible effect as far as effective cleaning procedures can be applied to recover initial permeate flux (see Section 6.2.3.3).

In gas and vapor separation with microporous ceramic membranes, the driving force is still the pressure gradient across the membrane, but this parameter is not a determinant for mass transfer as in liquid filtration. Depending on pore size, viscous flow, Knudsen flow, or configurational diffusion are the main mechanisms involved in gas transport. For condensable gases and vapors, adsorption phenomena, surface diffusion, and capillary condensation are other factors influencing molecular separation. In other respects, gas separation with dense ceramic membranes is a totally different mechanism based on ionic transport through a dense ceramic structure. The chemical potential or the electrical field gradient across the dense membrane material determines the selective transport of ionic species. The chemical and crystalline structure stability as well as the mechanical resistance under operating conditions are the major parameters quantifying the performance of dense inorganic membranes.

### 6.2.2.1 Liquid Filtration

Microfiltration and ultrafiltration are the two main filtration techniques for which ceramic membranes have been widely used to date. As described in Section 6.2.1.2, MF and UF ceramic membranes exhibit macro- and mesoporous structure, respectively, which result from packing and sintering of ceramic particles. Liquid flow in such porous media is convective in nature and the simplest description of permeation flux,  $J$ , is given by the Darcy's equation [20]:

$$J = -L_p \, dP/dx \quad (6.1)$$

where

$L_p$  ( $\text{m}^3/\text{m}^2 \text{ Pa s}$ ) is the permeability coefficient

$dP/dx$  is the driving force expressed as the pressure gradient across the membrane

In fact  $L_p$  contains information about the porous structure (porosity, pore size, and tortuosity) of the membrane as well as the viscosity of the filtrated liquid varying nonlinearly with the temperature. For the sake of comparison between membranes exhibiting different thicknesses, the membrane thickness  $\Delta x$  can be introduced in the permeability coefficient whose dimension becomes ( $\text{m}^3 \text{ m}/\text{m}^2 \text{ Pa s}$ ).

In the case where pore can be considered as cylinders with the same radius, the volume flux through the pore may be described by the following Hagen–Poiseuille equation, for example, when the porous structure is obtained by a templating method, as shown in Figure 6.8c:

$$J = \frac{\varepsilon^* r^2}{8\eta\tau} \frac{\Delta P}{\Delta x} \quad (6.2)$$

where

$\varepsilon^*$  is the surface porosity

$r$  is the pore radius

$\eta$  is the viscosity of the filtrated liquid

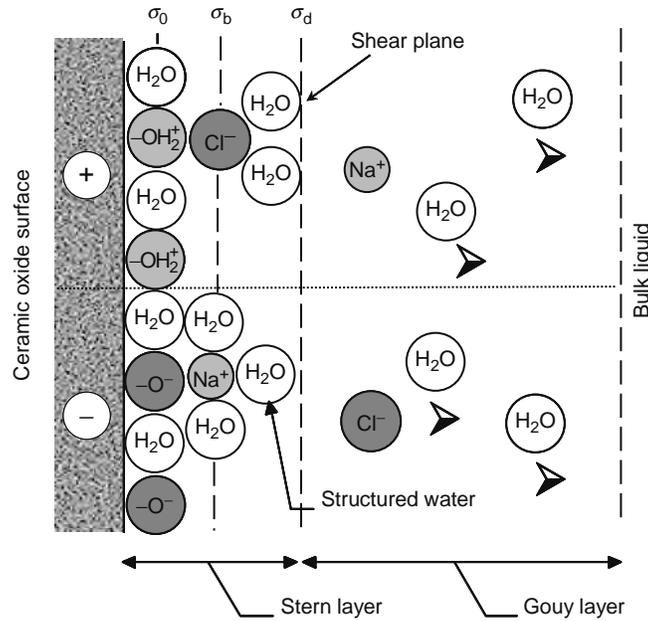

$\tau$  is the pore tortuosity

$\Delta P$  is the pressure gradient across the membrane

$\Delta x$  is the membrane thickness

The surface porosity is equal to the ratio of the pore area to membrane area multiplied by the number of pores. In most cases volume flux through ceramic membranes can be best described by the Kozeny–Carman relationship, which corresponds to a system of close packed spheres (see Figure 6.8a):

$$J = \frac{\varepsilon^3}{K\eta S^2(1-\varepsilon)^2} \frac{\Delta P}{\Delta x} \quad (6.3)$$

**FIGURE 6.11** Schematic representation of positively or negatively charged double layer forming in aqueous media on ceramic oxide surface in presence of electrolytes.

where

$\varepsilon$  is the volume fraction of the pores

$S$  is the internal surface area

$K$  is the Kozeny–Carman constant, which depends on the shape of the pores and the tortuosity

Equations 6.1 through 6.3 are no more applicable for low UF and NF ceramic membranes, typically when pore sizes are close or in the nanometer range. In this case, surface energy and electrostatic interactions influence mass transfer and retention in a non-negligible manner. In aqueous media, ceramic oxide surface exhibits an amphoteric behavior leading to a negatively or positively charged surface double layer (Figure 6.11) depending on the pH of the feed liquid and the isoelectric point of the ceramic in contact with this liquid. Accordingly, an electrical potential, also called zeta potential, establishes between the charged double layer and the solution, whose barrier intensity depends on the ionic strength of the solution. When pore radius is in the same order of magnitude than the zeta potential barrier, transport of ionic species is affected by the fixed charge of the membrane. Ions with the same charge as the fixed ions in the membrane are excluded and cannot pass through the membrane. This effect is known as the Donnan exclusion and can be described by equilibrium thermodynamics from which the chemical potential of the ionic species can be calculated in the membrane and in the solution, and then the concentration of the different species. If the concentration in the feed is low and the concentration of the fixed charge is high, the Donnan exclusion is very effective.

When a driving force (transmembrane pressure) is applied to these low UF and NF membranes, a basic irreversible thermodynamics approach is most often used to describe the solvent flux, which can be calculated by using Equation 6.4:

$$J_V = \frac{L_p}{\Delta x} (\Delta P - \sigma \Delta \Pi) \quad (6.4)$$

In this equation compared to Equation 6.1, the osmotic pressure,  $\Delta \Pi$ , of the feed solution and a reflection coefficient,  $\sigma$ , have been introduced to account for the counter flux due to the difference in concentration of small solutes (molecule or ion) between the feed phase and the permeate phase.

Concerning the transport of solute, a first equation can be written for neutral species that accounts for the diffusion and the convective transport of species through the membrane:

$$J_S = \omega(C_m - C_p) + (1 - \sigma)J_V \bar{C} \quad (6.5)$$

where

$\omega$  is the permeability coefficient

$(C_m - C_p)$  is the concentration gradient across the membrane

$\bar{C}$  is the mean concentration in the membrane for the solute

For electrically charged membranes and when ionic solutes are present in the feed liquid, transport for each species should be appropriately described by the general Nernst–Planck equation:

$$j_i = -D_{i,p} \frac{dc_i}{dx} - \frac{z_i c_i D_{i,p}}{RT} F \frac{d\psi}{dx} + K_{i,c} c_i j_v \quad (6.6)$$

where

$D_{i,p}$  is the diffusion coefficient of species  $i$  in membrane pores

$c_i$  is the concentration of this species in the membrane and  $z_i$  its charge number

$F$  is the Faraday constant

$\psi$  is the electrical field

$K_{i,c}$  is the friction coefficient due to convective transport of species by the volume flux  $j_v$

Actually, as schematized in Figure 6.12, species will be retained by the membrane according to their size (sieving effect) or to their electrical charge (Donnan exclusion). Accordingly, ionized small molecules can be retained even if they are smaller than pore size. For a mixture of multivalent and monovalent co-ions in the feed, multivalent co-ions are retained due to their higher electrical charge, while a part of monovalent co-ions pass through the membrane with counterions to fulfill charge equilibrium criterion on both sides of the membrane. This may lead to a negative retention of monovalent co-ions.

Retention of ionic species modifies ionic concentrations in the feed and permeate liquids in such a way that osmotic pressure or electroosmotic phenomena cannot be neglected in mass transfer mechanisms. The reflexion coefficient,  $\sigma$ , in Equations 6.4 and 6.5 represents, respectively, the part of osmotic pressure force in the solvent flux and the diffusive part in solute transport through the membrane. One can see that when  $\sigma$  is close or equal to zero the convective flux in the pores is dominant and mostly participates to solute transport in the membrane. On the contrary when  $\sigma$  is close or equal to 1, mainly diffusion phenomena are involved in species transport through the membrane, which means that the transmembrane pressure is exerted across an almost dense structure. Low UF and NF ceramic membranes stand in the former case due to their relatively high porous volume and pore sizes in the nanometer range. Recently, relevant results have been published concerning the use of a computer simulation program able to predict solute retention and flux for ceramic and polymer nanofiltration membranes [21].

Furthermore, as ceramic membranes offer specific advantages for organic solvents filtration, it is worthwhile considering the involved liquid/solid interaction phenomena when organic solvents are flowing through porous ceramic oxide structures made of small mesopores or micropores. The porous structure of ceramic oxide membranes can be considered as a high-energetic surface medium and the interaction force per interfacial area may be quantified using different surface energy concepts as the disjoining pressure or the density variation resulting from molecular ordering of solvent molecules at the

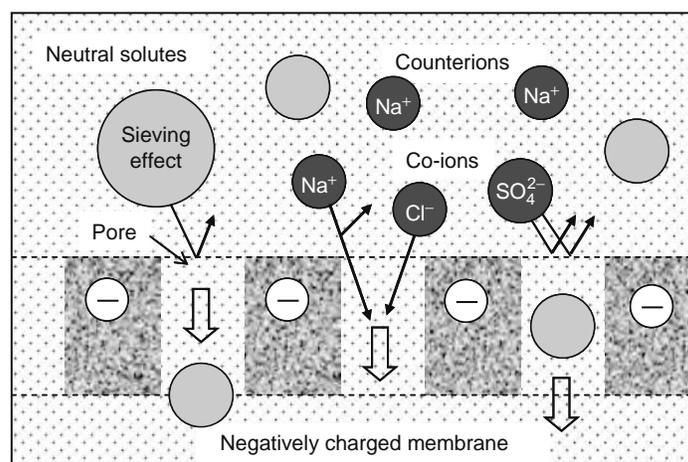

FIGURE 6.12 Schematic representation of retention mechanisms involved in aqueous medium for low UF and NF ceramic membranes.

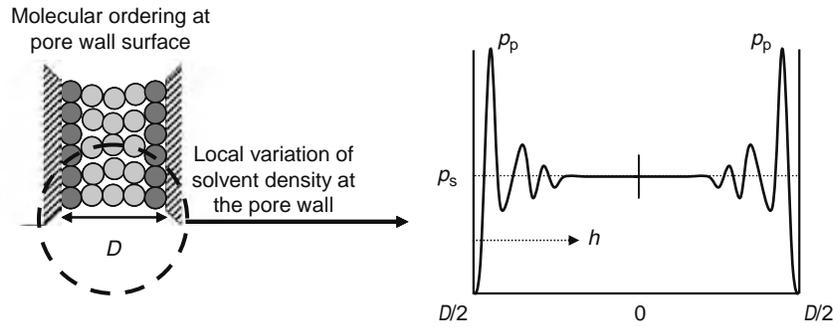

FIGURE 6.13 Local variation of solvent density near pore walls due to solvation and structural forces.

solid interface [22]. Accordingly, it is useful to compare solvation forces for aqueous systems and for nonaqueous systems. In the former case, repulsive hydration forces arise from strongly H-bonding surface groups ( $-\text{OH}$  for ceramic oxides) and they are affected by the presence of electrolytes. In the case of nonaqueous liquids in contact with high-energetic surfaces, the magnitude of attractive (adhesive) or repulsive forces are affected by molecular ordering which in turn depends on the shape and nature (polar or nonpolar) of molecules. With nonpolar, roughly spherical and rigid molecules like  $\text{CCl}_4$ , benzene, toluene, or cyclohexane, beyond the adhesive force at the solid interface there is the possibility of a long-range molecular ordering with a characteristic length of several molecular dimensions. On the contrary, nonpolar, small flexible molecules such as alkanes may be considered as being internally liquid-like and they have no need to reorder resulting in short-range structure not exceeding two or three molecular packing dimensions. For polar solvents like alcohols the repulsive solvation forces are predominant at short distances near the solid interface, while the DLVO theory applies at large distances. Considering now the change in liquid density profile near the solid interface due to solvation or structural forces (Figure 6.13), it is likely that solvent flux may be affected when pore sizes are in the same order of magnitude that the characteristic length for molecular ordering at pore wall surface.

Basically, for nonpolar liquids on more polar substrates, as it is the case for most of organic solvents in contact with a ceramic oxide surface, substrate-wetting films are stable. From consideration of the surface energies involved in the wetting processes of solid substrates, it can be readily shown that they can be related to the liquid–vapor surface tension ( $\gamma_{\text{lv}}$ ) and contact angle ( $\theta$ ). Thus, a liquid will stick to a solid if  $\theta < \pi$  corresponding to a work of adhesion,  $W_a = \gamma_{\text{lv}} (\cos \theta + 1)$ , and then for total wetting,  $\theta = 0$  and  $W_a = 2\gamma_{\text{lv}}$ . In general, the enhanced attractive interaction between a liquid and a solid substrate improves wetting. In the case of a porous substrate, a useful parameter accounting for liquid penetration in the pores is the capillary pressure that must be passed for observing liquid flowing through a membrane:

$$P_c = 2\gamma_{\text{lv}} \cos \theta / r_p \quad (6.7)$$

In summary, for ceramic membranes exhibiting low pore dimensions, penetration of liquids including organic solvents in the membrane pores is governed first by the capillary pressure. This may be the reason why zero flux may be observed at too low transmembrane pressure with ceramic nanofilters. Moreover, when the characteristic length for molecular ordering at the pore wall is on the same order as the pore size, the disjoining pressure of wetting films cannot be neglected. It results in repulsive forces with aqueous or polar solvents having a positive contribution to the driving force, while attractive (adhesive) forces encountered with nonpolar solvents will have a negative contribution with an additional resistance to permeate flux. Presently, the few results available in the literature confirm that organic solvent filtration with ceramic nanofilters does not obey the Hagen–Poiseuille or Kozeny–Carman equations [23]. Actually, finding a reliable relationship, able to describe organic solvent permeation through low UF and NF ceramic membranes, would require further experimental results.

For all the aforementioned liquid filtration technologies, membrane selectivity is most often expressed as the membrane retention,  $R$ , toward the species to be separated.

$$R = \frac{C_f - C_p}{C_f} = 1 - \frac{C_p}{C_f} \quad (6.8)$$

where

$C_f$  is the concentration of the species in the feed

$C_p$  is the species concentration in the permeate

$R$  is the dimensionless parameter that varies from 100% for an ideal semipermeable membrane to 0% when the species and the solvent pass freely through the membrane

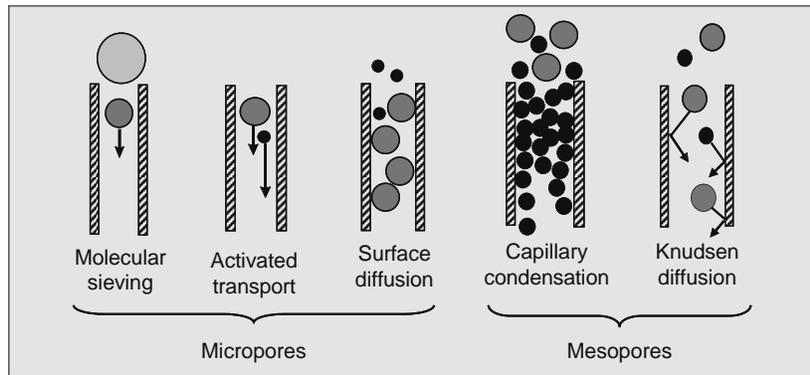

FIGURE 6.14 Different mechanisms involved in gas and vapor transport through meso- and microporous ceramic membranes.

### 6.2.2.2 Gas and Vapor Transport across Porous Membranes

Basic mechanisms involved in gas and vapor separation using ceramic membranes are schematized in Figure 6.14. In general, single gas permeation mechanisms in a porous ceramic membrane of thickness  $\ell$  depend on the ratio of the number of molecule–molecule collisions to that of the molecule–wall collisions. In membranes with large mesopores and macropores the separation selectivity is weak. The number of intermolecular collisions is strongly dominant and gas transport in the porosity is described as a viscous flow that can be quantified by a Hagen–Poiseuille type law:

$$j_v = \frac{\varepsilon}{8\eta\tau} \frac{r^2 P}{RT\ell} \Delta P \quad (6.9)$$

where

$R$  is the gas constant

$T$  is the temperature

$P$  the mean pressure in the membrane has been introduced to account for specific gas phase behavior in the porosity,  $\varepsilon$  (Equation 6.9 is similar to Equation 6.2 for liquids)

On the contrary, when the number of molecule to wall collisions is strongly dominant (mesopores), gas transport is described by the Knudsen flow. According to the Equation 6.10

$$j_K = \frac{2\varepsilon r}{3\tau\theta_k\ell} \sqrt{\frac{8}{\pi RTM}} \Delta P \quad (6.10)$$

where

$M$  is the molecular weight of the gas molecule

$\theta_k$  accounts for the wall roughness

In this case the permeation is proportional to the average pore radius  $r$  and inversely proportional to  $M^{0.5}$ , but is independent of the mean pressure  $P$  that is an important difference from viscous flow. The separation selectivity between two gases will be proportional to  $(M_2/M_1)^{0.5}$ . In the case of vapor transport in mesopores, another mechanism that may occur is the capillary condensation leading to selective filling of pores by a molecule and preferential transport of this molecule.

In comparison with the two previous cases, a much more complex description should be necessary for configurational diffusion of gases through microporous membranes. Here the driving force must be described in terms of a chemical potential gradient, which is coupled to partial pressure via adsorption isotherms. In fact, several mechanisms can operate simultaneously requiring simplifying assumptions. Surface diffusion at low temperature and activated transport at high temperature are the two main mechanisms exploited for gas and vapor separation with ultramicroporous membranes, such as zeolite membranes. At low occupancy of molecules in the pores (Henry regime) the gas flux through the membrane can be described by the general equation (Equation 6.11):

$$j_g = k \frac{D_0 K_0 q_{\text{sat}}}{\ell} \exp\left(-\frac{E_d - Q_a}{RT}\right) \Delta P \quad (6.11)$$

where

$k$  is the geometric correction factor

$D_0$  is the intrinsic diffusion coefficient of gas molecules

$K_0$  is the Langmuir constant

$q_{\text{sat}}$  is the amount of adsorbed gas

$E_d$  is the activation energy (Arrhenius relation for the diffusion coefficient  $D$ )

$Q_a$  is the heat of adsorption (van't Hoff relation for Langmuir constant  $K$ )

When kinetic diameters of molecules are almost similar to pore sizes, a molecular sieve effect is observed. In molecular sieve membranes, such as microporous carbons, the pore opening is sufficiently small relative to the size of the diffusing molecule, so that repulsive forces dominate and the molecules require activation energy to pass through the constrictions. In this region of activated diffusion, molecules with only slight differences in size can be effectively separated through molecular sieving.

In summary, one can see that separation selectivity for gas and vapor molecules depends on the category of pores (mesopores, supermicropores, and ultramicropores) and on the related transport mechanisms. Either size effect or preferential adsorption effect (irrespective of molecular dimension) is involved in selective separation of multicomponent mixtures. The membrane separation selectivity for two gases is usually expressed either as the ratio between the two pure gas permeation fluxes (ideal selectivity) or between each gas permeation flux measured from the mixture of the two gases (real selectivity). More detailed information on gas and vapor transport in porous ceramic membranes can be found in Ref. [24].

### 6.2.2.3 Ion-Conducting Membranes

Dense ceramic ion-conducting membranes (CICMs) are emerging as an important class of inorganic membranes based on fluorite- or perovskite-derived crystalline structures [18]. Most of the ion-conducting ceramics discovered to date exhibit a selective ionic oxygen transport at high temperatures  $>700^\circ\text{C}$ . Ionic transport in these membranes is based on the following successive mechanisms [25]:

1. Conversion of molecular oxygen in ionic species on the membrane feed side

2. Migration of vacancies,  $V_a^{\bullet\bullet}$ , in the dense material and transfer of electronic species,  $e$ , either in the dense material or in an external circuitry, depending on the conduction mode (mixed ionic–electronic or purely ionic).
3. Recombination of ionic oxygen species on the permeate side with production of molecular oxygen

The oxygen flux can be pressure or electrically driven as shown in Figure 6.10. For a mixed ionic–electronic conduction, both ions and electron are transferred in the ceramic under an oxygen pressure gradient. On the contrary, for a purely ionic conducting material, an external electrical circuitry is used for electron transport. These membranes are very selective and able to produce pure oxygen ( $>99\%$ ) from air. More recently proton–conducting ceramics at high temperature have been described in Ref. [26]. Although performances of these membranes need to be improved, a very high selectivity is expected in hydrogen separation. The flux of oxygen or hydrogen in these membranes is expressed in Equations 6.14 and 6.15:

$$J_{\text{O}_2} = -\frac{RT}{16F^2L} \int_{p_{\text{O}_2}^I}^{p_{\text{O}_2}^{II}} t_i t_{el} \sigma_t d \ln p_{\text{O}_2} \quad (6.14)$$

$$J_{\text{H}_2} = -\frac{RT}{4F^2L} \int_{p_{\text{H}_2}^I}^{p_{\text{H}_2}^{II}} t_i t_{el} \sigma_t d \ln p_{\text{H}_2} \quad (6.15)$$

where

$L$  is the membrane thickness

$p^I$  and  $p^{II}$  are the partial pressures of oxygen or hydrogen at the two sides of the membrane

$\sigma_t$  is the total conductivity

$t_i$  and  $t_{el}$  are the ionic and electronic transport numbers

### 6.2.3 COMMERCIALY AVAILABLE CERAMIC MEMBRANES AND IMPLEMENTATION IN DEVICES

The number of commercially available inorganic membranes has considerably increased over the past 20 years. Although ceramic membranes are presently the most widespread on an industrial scale, metallic, glass, or carbon membranes are also for sale from membrane suppliers. A non-exhaustive list of major inorganic membrane suppliers are given in Table 6.1. Beyond these inorganic membrane core industries whose activity is focused on membrane and module design, there are a lot of companies involved in membrane and filtration activities, offering among others inorganic membrane-based technologies.

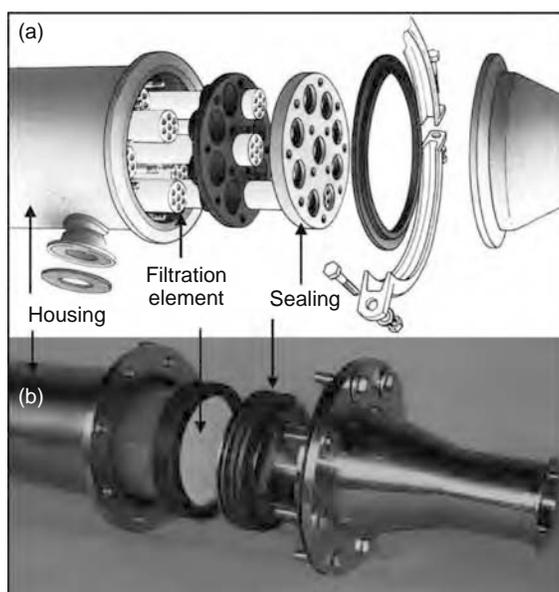

#### 6.2.3.1 Membrane Modules

As previously mentioned, most of ceramic membrane elements are produced under cylindrical shapes, i.e., tube, multichannel, and monolith elements. Membrane modules are composed of one or more of these filtration elements, inserted in stainless steel housing (Figure 6.15). Plastic housings are also used, but stainless steel is often preferred to fully exploit specific properties of inorganic membranes, in particular, their ability to work in tough chemical and temperature conditions. Sealing of filtration elements in modules is a critical point so far as it must suit operating conditions of ceramic membranes, i.e., long durability in use under high temperature, aggressive chemicals, organic solvent environment, sterilization, and cleaning procedures. Membrane suppliers have their own technology for sealing the membrane elements in modules, which can be more or less sophisticated depending on the element geometry and the size of the modules.

Compared to modules based on cylindrical elements, flat ceramic membrane modules are not developed in a large extent and are limited to date to small liquid volume treatment [27]. Flat ceramic membranes are generally implemented as disks in laboratory scaled cells, offering a limited filtration surface area. Indeed a diameter of 90 mm that is one of the largest available dimensions for these membrane disks results in a filtration surface of  $\sim 56 \text{ cm}^2$ . Anopore alumina membranes supplied by Whatman or ATZ ceramic membrane disks with zirconia or titania top-layers from Sterlitech are typical examples of these commercially available flat ceramic membranes. Sterlitech ATZ ceramic membrane disks and the corresponding membrane holder are shown in Figure 6.16.

Interestingly, an innovative design has been described recently by the Fraunhofer IGB, Germany [27], allowing the production of flat membrane modules with an effective filtration area of  $1 \text{ m}^2$  (Figure 6.17a). This concept is based on novel flat ceramic supports specially processed to produce corrugated channels and able to receive micro- and ultrafiltration membranes (Figure 6.17b).

In a general way, most of ceramic membrane modules operate in a cross-flow filtration mode [28] as shown in Figure 6.18. However, as discussed hereafter, a dead-end filtration mode may be used in some specific applications. Membrane modules constitute basic units from which all sorts of filtration plants can be designed not only for current liquid applications but also for gas and vapor separation, membrane reactors, and contactors, which represent the future applications of ceramic membranes. In liquid filtration, hydrodynamics in each module can be described as one incoming flow on the feed side  $Q_f$ , which results in two

**FIGURE 6.15** Examples of ceramic membrane modules. (a) Multi-elements module from Orelis and (b) single-element module from CeraMem.

**FIGURE 6.16** Ceramic membrane disks and membrane holder from Sterlitech.

outgoing flows related to retentate  $Q_r$  and permeate  $Q_p$  sides, respectively. The permeation flux  $J$  per membrane surface unit is directly calculated from  $Q_p$ . Two important parameters account for hydrodynamic working conditions of a module, one is the flow velocity,  $\nu$ , in the module calculated as the ratio of the incoming flow  $Q_f$  ( $\text{m}^3/\text{s}$ ) by the hydraulic section of the module  $\Omega$  ( $\text{m}^2$ ), the other is the transmembrane pressure,  $P_{tm}$ :

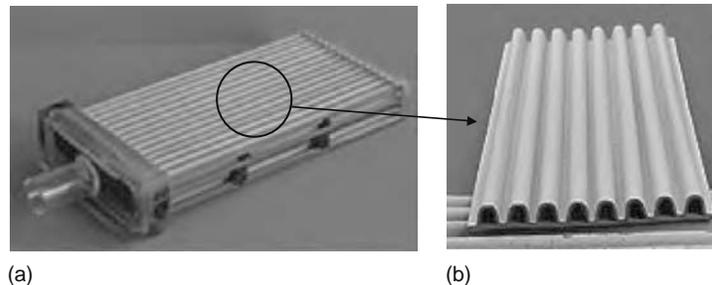

$$P_{tm} = \frac{P_i + P_r}{2} - P_p \quad (6.16)$$

where

- $P_i$  is the incoming pressure of the liquid in the module
- $P_r$  the pressure of the outgoing liquid
- $P_p$  the pressure in the permeate compartment

### 6.2.3.2 Modules Arrangement

In industrial plants, ceramic membrane modules are arranged in different ways based on the general principles used for the design of membrane processes. The simplest module implementation is the dead-end operation mode. Here, the feed is forced through the membrane, which implies that the concentration of rejected components on the feed side of the membrane increases continuously and consequently the quality and the flux of permeate decrease with time. The main advantage of the dead-end

**FIGURE 6.17** Flat membrane module with an effective membrane area of  $1 \text{ m}^2$  (a), obtained by assembling channel corrugated porous ceramic supports (b), from (IGB, 26).

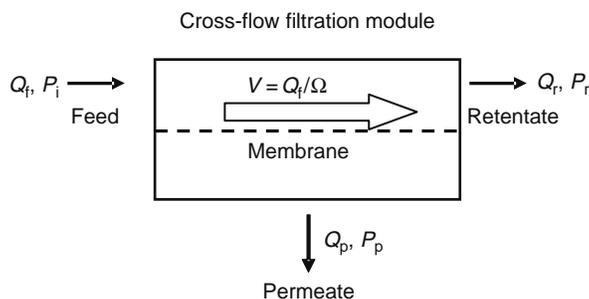

FIGURE 6.18 Schematic drawing of a module.

filtration mode is weak energy consumption. An example of a submerged module working in the dead-end filtration mode is shown in Figure 6.19. Usually, a cross-flow operation for the modules is preferable because of a lower fouling tendency relative to the dead-end mode and because it results in much higher permeate fluxes. In fact the choice between the two modes is related to the mass transfer coefficient that strongly depends on the bulk diffusion coefficient of the species retained by the membrane and the system hydrodynamics, in particular the cross-flow velocity. The logarithmic linear relationship (Equation 6.17) between measured permeate flux,  $J$ , in real conditions and Reynolds number,  $Re$ , may be helpful for choosing between the two operating conditions, dead-end or cross-flow filtration mode.

$$\ln J = a \ln Re, \quad \text{with} \left( Re = \frac{\rho \nu d_h}{\eta} \right) \quad (6.17)$$

The  $Re$  number accounts for both hydrodynamics and fluid characteristics, i.e., on the one hand cross-flow velocity,  $\nu$ , and hydraulic diameter,  $d_h$ , in the module; on the other hand dynamic viscosity,  $\eta$ , and mass density,  $\rho$ , of the fluid. Normally,  $Re > 2100$  guarantees a turbulent flow in the module and a minimum thickness for the concentration polarization layer. A small value of coefficient  $a$  means that  $\nu$  has a weak influence on  $J$ , so that a weak fluid velocity or even a dead-end filtration mode can be used. On the contrary, when the value of  $a$  is high ( $>0.5$ ), a cross-flow filtration mode with a high-fluid velocity is necessary.

Different module assembling and working conditions exist in the cross-flow filtration mode. For small- and medium-scale applications, the batch configuration is often followed with the possibility to perform diafiltration and concentration operations. As shown in Figure 6.20, retentate can be either concentrated in a recirculation loop or recycled continuously in the feed tank. An intermediate operating mode consists of recycling only a part of the retentate in the feed tank. Moreover, the possibility of adding water in the feed tank to compensate permeate flux results in a diafiltration process used for the elimination of unwanted species from the retentate. Another advantage of this configuration is that permeate or retentate can be easily recovered as the desired product. In short, batch filtration is a very versatile system able to adapt to many operating conditions and is widely used in many applications where the volume of liquid to be treated does not exceed a few tens of cubic meters per day.

Often a single-stage process does not result in the desired product quality and for this reason, permeate or retentate stream must be treated in a second stage. Then a combination of stages, called a cascade operation, with a more or less complex design can be imagined depending on whether the final permeate or retentate is the desired product. A simple multistage process consists of assembling a number of same modules in successive stages operating in a simple-pass mode (Figure 6.21). Hence

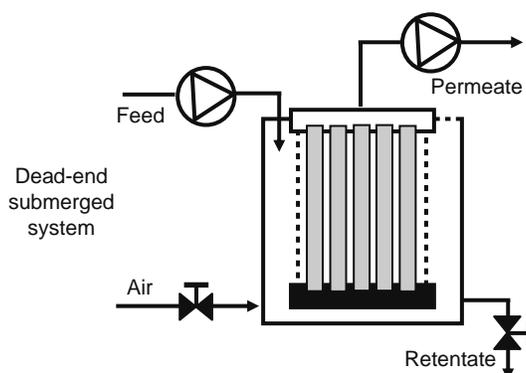

FIGURE 6.19 Schematic representation of a submerged module working in the dead-end filtration mode.

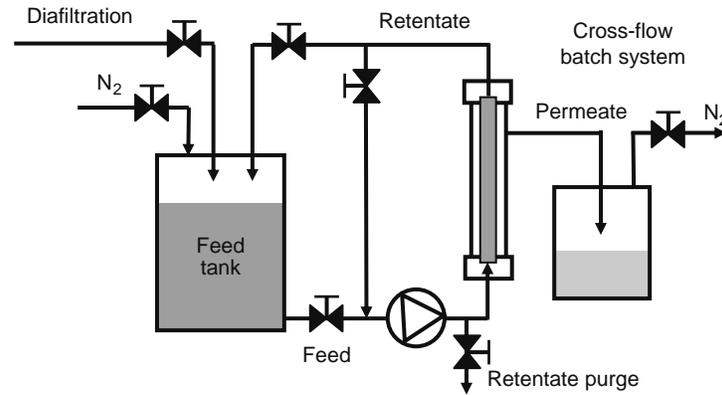

FIGURE 6.20 Schematic representation of a batch filtration system.

the volume of the feed decreases with the number of stages and logically the number of modules per stage is adapted to the loss of feed volume. In this arrangement the cross-flow velocity through the system remains virtually constant, but the pressure drop is important. This kind of system is usually implemented for the treatment of large quantities of liquid when permeate is the desired product.

A more complex and costly multistage system is when the feed flow is recycled several times on each stage. Two kinds of pumps are required in this case, one or more for plant feeding and a recirculation pump on each stage (Figure 6.22). Several advantages arise from this system compared to the simple-pass filtration mode. The flow velocity and pressure can be adjusted in every stage. Membranes with different characteristics can be implemented in two successive stages. The feed recycle system is more flexible than the single-pass system and is to be preferred in cases where severe fouling and concentration polarization occur as in microfiltration and ultrafiltration. With regard to the common applications of ceramic membranes (food and beverage industry, wastewater treatment, very turbid fluid pretreatment), the feed recirculation system is more often used than the simple-pass system.

### 6.2.3.3 Competitiveness of Ceramic Membranes

The design and implementation of a membrane process, whatever the nature of the membrane (polymer or ceramic), is a long procedure starting from membrane testing on a laboratory scale and ending in implementation of an industrial plant. It includes both technical and economical evaluation, which makes the membrane process viable or not compared to alternative separation processes. The overall costs are distributed in investment costs and running costs. As already mentioned ceramic membranes are more expensive than their polymeric counterpart and will result in higher investment costs, at least for the membrane system alone. However, the high investment cost can be balanced by a lower running cost when using ceramic membranes (i.e., less pretreatment, longer membrane lifetime, and more efficient cleaning and sanitizing conditions).

Indeed, in many cases the membrane system cannot be used directly and often pretreatment is necessary to facilitate the membrane process. Pretreatment is important and necessary in micro-, ultra-, and nanofiltration, while it is not that important for pervaporation (PV), vapor permeation (VP), or gas separation for which feed streams are usually much cleaner and do not contain many impurities. The cost of pretreatments can contribute appreciably to the overall costs. However, due to the intrinsic

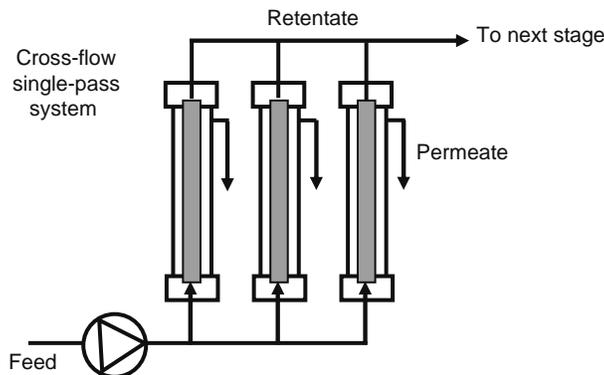

FIGURE 6.21 Schematic representation of a simple-pass modules stage.

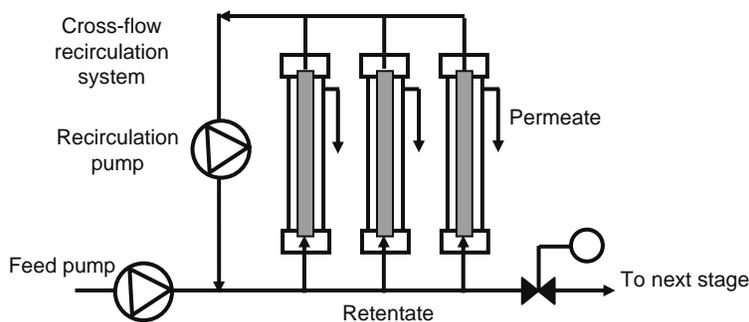

FIGURE 6.22 Schematic representation of a feed recirculation modules stage.

characteristics of modules and membrane material, ceramic membranes require less feed stream pretreatment and authorize very efficient cleaning and sanitizing procedures.

Two phenomena are responsible for flux decline during membrane operation with real fluids [20]. One is related to polarization phenomena (concentration and temperature polarization), which normally are reversible processes. Thus, at a finite time, when steady-state conditions have been attained, the flux stabilizes at a value always less than the original one. Membrane fouling is the second phenomenon responsible for flux decline. It consists of the deposition of retained particles, colloids, emulsions, suspensions, macromolecules, salts, etc. on/in the membrane. Fouling always results in a continuous (ir)reversible decrease of membrane flux with time and constitutes one of the major problem to be managed during filtration plant operation. This is a very complex phenomenon and the methods for reducing fouling must be adapted to the different used membranes and treated fluids. Several aspects such as pretreatment of feed solution, membrane and module characteristics, and operating parameters have to be anticipated during the process design, otherwise heavy cleaning procedures should be carried out on the membrane plant in operation.

The utmost advantage of ceramic membranes is to allow in-place chemical cleaning at high temperature, while using caustic, chlorine, hydrogen peroxide, ozone, and strong inorganic acids. Moreover steam sterilization can be used for sanitizing membrane plants. Another specific advantage of ceramic membranes is the possibility to be back-pulsed which is basically a permeate flow reversal technique to reduce fouling and to increase filtration efficiency. As shown in Figure 6.23, back-pulsing consists of periodically reversing the permeate flow by applying pressure to the permeate side of the modules. In this manner, the accumulated matter on the feed side of the membrane is periodically removed from the surface and carried away by the circulating fluid. Other physical methods recently investigated utilize gas bubbling [29] or ultrasound [30] to prevent fouling or for cleaning fouled membranes.

One can see that ceramic membranes differ from their polymeric counterparts by intrinsic properties (rigid porous structure, high-temperature resistance, high-chemical resistance to aggressive aqueous and organic media, insensitiveness to biological attack) which are based on the inorganic nature of the membrane material. In current applications mainly devoted to the treatment of liquids, general principles of membrane processes apply equally to ceramic and polymeric membranes. For both membrane categories, the modules are implemented in industrial plants, following the same hydrodynamic laws and mass transfer mechanisms. Most often, the choice of ceramic membranes is driven by economical considerations and despite its inherent qualities ceramic membranes are considered as expensive compared to polymeric ones. Nevertheless, a large number of applications are described in Section 6.3, showing that in many cases ceramic membranes have been considered as competitive compared to alternative processes.

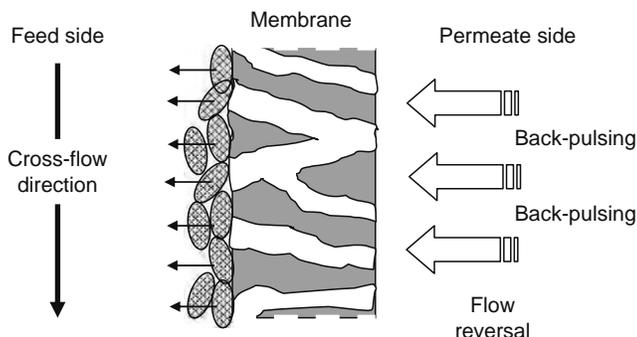

FIGURE 6.23 Schematic representation of permeate back-pulsing allowing in-place removal of accumulated matter on membrane surface.

## 6.3 CURRENT APPLICATIONS OF CERAMIC MEMBRANES

The number of applications of ceramic membranes has continuously been increased over the past 20 years. Even if data on the extent of installed plants are not directly available, the sales in inorganic membranes are estimated between €250 and €350 million in 2005 with a potential growth of 10%–15% a year. Many references on the use of ceramic membranes can be found in the proceedings of the successive International Conferences on Inorganic Membranes as well as in the books of Bhave [1], and Burggraaf & Cot [3]. The aim of this part is not to provide an exhaustive overview of all possible applications but to focus on relevant examples of current ceramic membrane processes. These applications have been classified into three main groups: (i) the treatment of waste liquids and gases; (ii) liquid processing including drinking water, domestic water, and food beverages; (iii) product recovery in various industries. Due to its robustness, ceramic membranes are developing faster in the treatment of liquid wastes than in other sectors. Actually, the demands of efficient liquid waste treatment are being pushed up both by regulatory and cost pressures to reduce environmental impact of human activity [31,32]. In a general way, there are many water shortage problems currently in the world so that the recycling of wastewater streams is an urgent necessity. In liquid processing, the sector of food beverages is the first one where ceramic membranes have been developed at the industrial scale, in particular in the dairy industry. Actually the demand for more secure membranes is increasing in the food industries as an alternative to polymer membranes that are less amenable to sanitary requirements. Finally ceramic membranes can be used in many industries, directly for the recovery of various products, not only from micrometer-sized species (mineral particles, microorganisms, macromolecules, etc.) down to nanometer-sized species (viruses, colloids, molecules, ions), but also as a filtration pretreatment before other separation techniques including polymer membranes.

### 6.3.1 TREATMENT OF WASTE LIQUIDS AND GASES

#### 6.3.1.1 Cross-Flow Filtration

The demand for industrial water in developed countries is increasing continuously in comparison with the limited natural resources. In recent years, recovery and reuse of industrial wastewater has arose as one of the important economical and ecological issues for a sustainable economy, the challenge in the modern technology being to allow industry to move toward the “zero discharge” concept. Membrane technology can afford viable solutions to the problem of water recycling in numerous industrial processes. Beyond the large availability and versatility of polymer membrane processes, the performance of ceramic membranes has considerably improved during the last 10 years. They are now able to provide long and reliable service life in many processes where polymer membranes cannot withstand operating conditions including the cleaning procedures, in terms of mechanical, chemical, and temperatures resistances. Moreover, the presence of abrasive particles, extreme pH conditions, organic solvents, and an elevated temperature in certain industrial wastewater effluents renders compulsory the use of inorganic membranes in the implementation of membrane processes.

A number of application areas have been identified in which cross-flow filtration with ceramic membranes revealed competitive compared to other separation processes [33]. Several cases can be mentioned: for example, removal of heavy metals from metal-finishing shop wastewater and treatment of spent chemical baths; heavy metal removal from acid mining drainage; recycling of laundry water by removing dirt, oil, and metals from wash water; treatment of wastewater chemical planarization of semiconducting; treatment and recycling of lubricating liquids used for cutting tools in mechanical industry; and in a general way all sorts of cleaning and rinsing waters from food and beverage processing industries. The following examples are representative of the current developments in the treatment of industrial waste liquid streams with ceramic membranes. Textile printing is a water-consuming industry where membranes and, in particular, ceramic membranes are well-adapted techniques for process intensification [34–36]. Ceramic membranes are also used for recycling process water in basic domestic activities like laundries [37] as well as in advanced industrial processes like polishing and washing stages of lens [38]. Ceramic membranes participate also to water and chemicals recovery in the automotive industry [39]. For example, a mean volume of 500 L of water per car body is used in pretreatment before electrophoretic painting. In this process, ceramic nanofilters have been chosen for water recycling due to the capacity of enduring working environment with long-service lifetime. New applications are also arising thank to the tight cut-off characteristics of ceramic nanofilters. Enormous volumes of bleach pulp effluent and black liquor are produced in kraft pulp mills. The bleaching process is highly water-consuming, while black liquor is regarded as a bottleneck by-product, which is usually burned in a recovery boiler after concentration by evaporation. Nano- and ultrafiltration techniques using ceramic membranes appear as efficient methods for water recycling in the bleach pulp process and lignin recovery from black liquor [40,41].

Another domain in which membrane separation technologies can afford viable solutions in the near future is the treatment of domestic wastewater [42]. Here, membranes are considered as too expensive and the technology is too sophisticated for sewage treatment. Nevertheless recent works by the European Space Agency [43] have shown that membrane technology including a ceramic membrane stage can cope with the life-support needs and isolation constraints during long-duration missions in space or in isolated scientific bases like in Antarctica. These space-related technologies including membranes used

for the treatment of wastewater should benefit to our daily lives by providing innovative and efficient solutions for domestic wastewater treatment.

### 6.3.1.2 Membrane Bioreactors

The membrane bioreactor (MBR) technology is a real alternative to pure filtration processes for the treatment of wastewater and industrial effluents. An MBR is the combination of an activated-sludge process with a membrane filtration. MBRs are composed of two primary parts: the biological unit responsible for the biodegradation of the waste compounds and the membrane module responsible for the physical separation of the treated water from mixed liquor. These systems are implemented based on two main configurations (Figure 6.24). The first (integrated) configuration consists of outer skin membranes that are internal to the bioreactor (Figure 6.24a). The driving force across the membrane is achieved by pressurizing the bioreactor or creating negative pressure on the permeate side. In the second (external) configuration, the mixed liquor is recirculated through a membrane module that is outside the bioreactor. In this case, the driving force is the pressure created by the high cross-flow velocity along the membrane surface (Figure 6.24b). Current available ceramic membranes having internal membrane top-layers are more adapted to the second MBR configuration.

There are a large number of potential applications of the MBR technology for the treatment of wastewater from agricultural and agri-industry sources [44]. Manure and wastewater from livestock can be treated by a technique coupling anaerobic digestion with an aerobic/anoxic membrane bioreactor, producing water for direct reuse or safe discharge. Wastewater generated from food processing industries such as slaughterhouses, meat, dairy, egg, and potato processing could potentially be treated with MRBs resulting in compact systems producing high-quality reusable water. Also effective removal of nitrates,

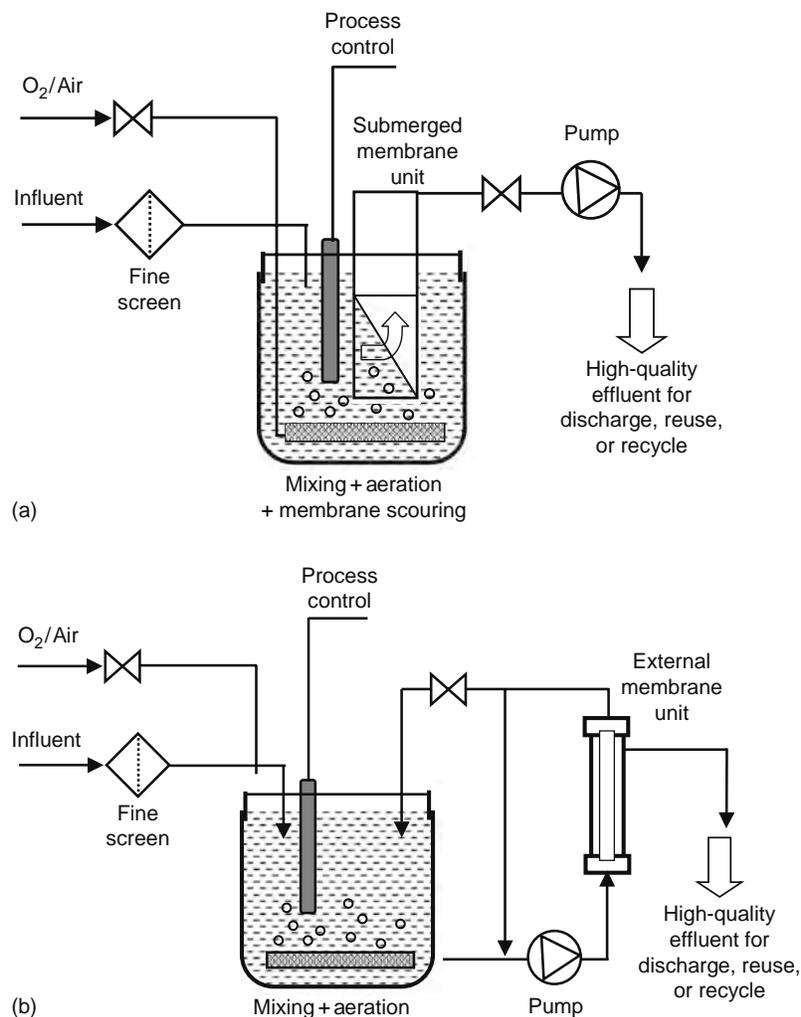

FIGURE 6.24 Membrane bioreactors configurations. (a) Internal outer-skin membranes and (b) outside membrane module.

herbicides, pesticides, and endocrine disrupting compounds may be achieved by MBRs. In drinking water treatment, either biological (bio-denitrification) or physicochemical (reverse osmosis, ion exchange, electrodialysis) techniques can be used for removal of nitrates. The advantage of coupling biodegradation and membrane separation in the MBR concept is to allow the removal of organic matter and the complete conversion of nitrates into nitrogen gas in a one-step relative easy operation. Another example of MBR utilization is the treatment of acid mine drainage. These drainages typically contain dissolved metals at high concentration and more than 3 g/L sulphate. The use of sulphate reducing bacteria (SRB) has been proposed as an alternative to hydroxide precipitation. Generally, MBRs can afford viable solutions to the treatment of industrial waste streams containing high organic loading, and very specific and difficult to treat compounds.

MBR are implemented with MF or UF membranes. Several types and configuration of membranes are used, including tubular, plate and frames, rotary disk, hollow fiber, organic, metallic and ceramic membranes [45]. However, ceramic membranes offer inherent advantages over polymeric membranes (possible high-sludge concentration, very efficient cleaning procedures, resistant to microorganisms) for this technology [46]. Although they have suffered from their high prices in the past, low-cost ceramic cross-flow membrane modules were successfully tested, able to promote a low-cost ceramic air lift MBR [47]. Large (200 mm hydraulic diameter by 1500 mm long), high surface area (15–28 m<sup>2</sup> depending on cell size) silicon carbide monolith membranes are envisioned in this application with projected membrane price in the range of €200/m<sup>2</sup>. The modules could be used in either a submerged MBR or an external airlift configuration. Sewage treatment [48] should be an attractive market for MBRs based on this new generation of ceramic membranes exhibiting low fouling behavior, high cleaning ability, and long durability.

### 6.3.1.3 Air Purification and Hot Gas Filtration

At the boarder line with ceramic membrane filtration, air purification and hot gas filtration using ceramic filters are technologies attracting significant attention in a wide variety of domestic applications and industrial processes [49–53]. The main difference with membrane technologies is that ceramic gas filters operate in a dead-end filtration mode and often as particle traps. Conversely, a major concern with ceramic membrane and filter technologies is the increasing demand for ceramic porous elements with a high efficiency in the retention of very small species (molecules with membranes or nanoparticles with filters). Ordinarily, ceramic filters for gas application exhibit low-density structure with high porous volume and pore size of several micrometer. Particulate structures, fabric, or fibrous media and more recently foams are commonly used as in-line filters to remove particulate contaminants from process gases. Today, new designs are considered for gas ceramic filters based on ceramic porous structures already developed for cross-filtration with ceramic membranes. The major evolution of these new filters compared to other available filters is the submicronic pore size adapted to the treatment of nanoparticulate aerosols, which will be a big issue in the development of nanoparticle production and its utilization in nanotechnologies. The difficulties involved in operating these new filters include the high pressure drop due the tight porous structure of the filter and the evaluation of filter efficiency by measuring low nanoparticle number concentrations downstream. For fabrication and utilization reasons, decreasing filter media thickness to lower pressure drop is not ever practical, hence an alternative approach is the application of new concepts based on hierarchical asymmetric filters [54]. The development of characterization setup and methodology to evaluate the filtration performance are also important aspects to deal with for the future utilization of these new filters [55].

## 6.3.2 LIQUID PROCESSING

### 6.3.2.1 Drinking and Domestic Water

Water purification for producing drinking and domestic waters is a quite complicated process, which must be adapted to the multiple water resources available as surface or ground water. Due to considerable pollution of natural waters, more and more stringent requirements are applied to natural water treatment. Contamination cases where traditional technological systems are ineffective are increasing continuously. High selectivity of membrane processes and no pollution charged to the environment make these methods very attractive as alternative or complementary processes. Membrane are effective for the removal of suspended particles, precipitates caused by water hardness or salts, organic compounds, and microorganisms (bacteria, spores, even viruses). The basic problem involving the application membrane processes in the treatment of natural water is the decrease of yield with time due to concentration polarization layer and reversible or irreversible fouling phenomena. Periodical renewal of the membranes and cleaning of the filtration plants considerably increase the price of produced water so that a number of methods have been proposed to prevent fouling or at least to make longer the time between two cleaning operations by removing continuously accumulated matter on membrane surface. For example, to maintain high permeate fluxes over long periods of time, adsorbents or coagulants can be used in conjunction with filtration [56]. In general, current commercial ceramic membranes (MF, UF, and NF) are able to treat turbidity and to remove biocontaminants from natural water [57,58]. The modules accept highly turbid waters, stringent cleaning conditions and can take advantage of in-place back-pulsing.

Utilization of ceramic membranes for water purification started in the 1980s [59] with the implementation of small size membrane plants (5–100 m<sup>3</sup>/h). Imeca in France was one of the first membrane suppliers entering this market with inorganic membranes. This membrane technology is now developing at a larger industrial scale with, for example, the ceramic-membrane water-purification systems designed by NGK in Japan. This company trusts systems based on ceramic membranes, because they are producing water that is safer to use than polymer membrane-based systems. Effectively, the elements have superior mechanical strength, which prevents them from being easily damaged, and they have lower running costs. However, the relatively high initial cost for these systems is a major concern in applications where large volume of purified water a day must be delivered. Estimated prices for polymer membranes currently in operation for drinking water treatment are about 30–50 €/m<sup>2</sup> for micro- and ultrafiltration, and 15–30 €/m<sup>2</sup> for nanofiltration and reverse osmosis. In order to render ceramic membrane elements more cost-effective compared to those based on polymer materials, a number of membrane manufacturers develop large ceramic membrane monoliths offering a large filtration surface per element (see Section 6.2.1.1). Thus a long membrane lifetime, a high membrane surface to volume achieved in the modules as well as a high permeate flow are expected to reduce significantly both investment and running costs of ceramic membrane plants. Several tens of cubic meters per hour of purified water are expected for the larger planned elements, which will render this technology competitive in a near future for large water purification systems.

### 6.3.2.2 Food and Beverage Processing

Contrary to water treatment, general principles cannot be stated for food and beverage processing with membranes. Each sort of food and beverage is a very complex system with specific components interacting with each other so that membrane processes must be specifically adapted to each case. Accordingly, a more detailed description of membrane processes is provided hereafter for the current major applications, i.e., milk, to some extent beer and wine, and a number of other applications showing the continuous expansion of ceramic membrane technologies in food industries.

#### 6.3.2.2.1 Fractionation of Valuable Milk Components

Milk is of the utmost importance for human feeding. It contains about 2000 components, which have been thoroughly studied not only for their nutritional properties, but also for the potential utilization of some of them in pharmaceuticals. The milk industry has been the first food sector in which membrane processes have been implemented at an industrial scale. The earliest development dates back to the end of the 1960s with ultrafiltration plants devoted to whey concentration. Since this period, almost all the membrane processes ordinarily used in liquid treatment (micro-, ultra-, and nanofiltration, diafiltration, reverse osmosis, electro dialysis) have been applied to the treatment of milk and its derivatives. Both ceramic and polymer membranes are used in milk industry; however, the ceramic membranes offer specific advantages in terms of cleaning procedure and sanitary conditions [60]. Compared to polymer membranes, they are able to withstand better harsh cleaning conditions used in the milk industry. Indeed, in-place chemical cleaning at high temperatures, while using caustic, strong inorganic acids, chlorine, hydrogen peroxide, ozone, and steam sterilization, are as many procedures used at different stages of milk transformation and conditioning.

In some cases, ceramic membranes are an integral part of new processes in milk transformation. One example is the fractionation of globular milk fat by membrane microfiltration [61]. Separation of milk fat in small globules (SG) (diameter lesser than 2 μm) and in large globules (LG) (diameter greater than 2 μm) was realized by a patented process using special ceramic microfiltration membranes. Transformation in drinking milks, yoghourts, sour cream, camembert, Swiss cheese, and butters was realized from milks of which the fat content was adjusted from the SG or the LG fractions. These products exhibit significant differences in texture and organoleptic properties compared to traditionally manufactured products, which make them more attractive for consumers. Ceramic membranes with pore diameters of about 2 μm have been identified as very suitable for this application. Permeate fluxes in this case vary from 200 to 700 L/h m<sup>2</sup>, which make the process economically viable. In a more general way, milk fractionation will lead to a more efficient and diverse use of milk and membrane separation seems a logical choice for that [62]. In addition to the aforementioned separation and fractionation of milk fat from whole milk, removal of bacteria and spores from skim milk (cold pasteurization), concentration of casein micelles from skim milk, and recovery of serum proteins from cheese whey are as many operations that can be currently carried out with membranes. Thanks to the availability of new ceramic membranes with smaller cut-off and narrow pore size distribution, new milk component-based products are under development such as edible coatings, bioactive peptides, or dairy and nutritious beverages. However, fouling is still considered as the limiting factor in milk filtration requiring further work on new membranes, module design, fouling control, and modeling to achieve rational design of milk fractionation processes.

#### 6.3.2.2.2 Beer and Wine Cross-Flow Microfiltration

Filtration is an important step in beer production that is traditionally done with filter aids, usually Kieselguhr. The use of Kieselguhr, diatomeaceous earth in a form of silica, is, however, getting more unfavorable in several aspects because the filter aids have to be disposed of or regenerated. Disposal is not environmental friendly and is getting more and more expensive. Moreover dusty atmosphere resulting from Kieselguhr handling is hazardous for the workers. The filterability of beer is an

important parameter and poor filterability can lead to an increase in production cost and also be a big bottleneck concerning the production volume with a significant quantity of wasted beer and spent yeast. Ceramic cross-flow filtration processes have been proposed as a solution with systems able to recover more than half of previously wasted beer, to eliminate disposal costs and to minimize environmental impact. In addition they have the potential to create new revenue streams, as yeast is concentrated to make it more viable for use as a base in animal feed, human food supplements, or as an additive for pharmaceuticals.

Wine manufacturing is still a very traditional process in which filtering is a very tricky subject, especially for prestigious wines. However, one can say that nowadays fining and filtering have been accepted by winemakers as useful tools in building a better wine. The challenge in fining and filtering wines is elimination of unwanted flavors and particles, and preserving of all the components that will create the personality of a good wine [63]. Concerning filtration, winemaking consultants agree to say that wines should be filtered to the minimum necessary. As for beer, filtration of wine has been achieved for years by diatomaceous earth filters with the same pending problems. In the 1990s, cross-flow microfiltration emerged as a very promising technology for this purpose because of its ability to perform wine clarification/filtration/hygienization in one single step. At that time, microfiltration with ceramic membranes offered real advantages over classical filters. Indeed, ceramic membranes function better under pressure, handling 35%–50% throughput. They can be cleaned by a “cleaning in-place” procedure based on an automatic reverse permeate flush. They can work in a continuous mode 18–20 h/day. Finally they last two or three times longer than organic filters.

Most of ceramic membrane equipment suppliers have entered the beer and wine filtration market with membrane products adapted to the specificity of these products [64–66]. The pore diameter of available membranes ranges between 0.1 and 1.5  $\mu\text{m}$ , but the choice of pore size cannot be systematically categorized for each family of products, in particular for wines. In fact filtration requirements are not the same for red wines and white wines. Even, in each of these categories the quality properties of the final product are not exactly predictable and render the choice of the membrane pore size very uncertain. Adsorption of wine compounds on membrane surface also influence filtration effectiveness. Polysaccharides with polyphenols are usually the main responsible compounds of the fouling in wine clarification with membranes [67]. Moreover the retention of these compounds will affect the organoleptic characteristics of the filtrated wine so that their retention and their fouling effect must be reduced. Up to now, filtration tests have shown that 0.1  $\mu\text{m}$  for white wines and 0.2–0.4  $\mu\text{m}$  for red wines are the most recommended pore sizes. The choice of pore size about 0.4  $\mu\text{m}$  for beer filtration looks easier but fouling phenomena are still present [68]. The  $\beta$ -glucans contained in the beer seem to be the major factor for membrane fouling. When they are subjected to high shear stress, high pressure, and rapid cooling, they elongate and form hydrogen bonds resulting in a gel-layer formation on the membrane. In order to improve the filterability many breweries add flocculants before filtration and let them sediment to remove big particles. This flocculation/sedimentation step can impact membrane filtration negatively or positively depending on if membrane modules are sensitive or not to residual particles in the feed stream.

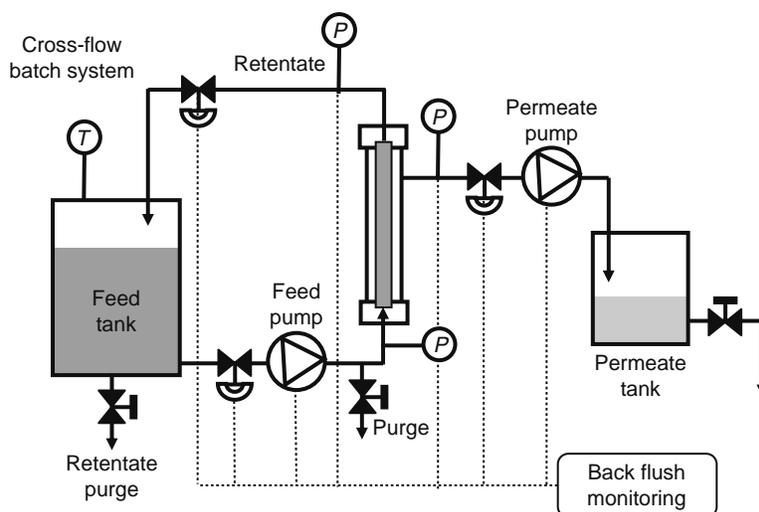

#### 6.3.2.2.3 Other Food Components

Many other applications for ceramic membranes exist in the food industry [1,69]. First, a wide range of fruit juices (apple, pear, peach, orange, grape fruit, pineapple, kiwi fruit, strawberry, cranberry, carrot, date, etc.) are now processed using ceramic membrane technologies, in particular, for clarification and pasteurization. However, flux decline due to membrane fouling is a major concern as it has been shown for apple juice [70]. Membrane technology has also shown high promise in starch processing industry for reducing evaporation costs, improving product recovery, and removing solids before wastewater treatment [71]. Effectively, membranes can be used in many operations of corn, potato, and wheat starch processing. For example, one of the most common applications for membranes in corn wet milling is the removal of residual lipids, proteins, and colorants from corn syrup [72]. It was reported [71] that in 1997 approximately 75% of the US-produced corn syrup was clarified using membrane filtration instead of conventional vacuum filtration. Moreover, the use of MF or UF with nominal pore sizes 0.01–0.1  $\mu\text{m}$  can provide pasteurization without use of heat, as most microorganisms are larger than this pore size. Here also, clarification and pasteurization are typical operations for which UF and MF ceramic membranes are of great interest [72]. Another interest in membrane filtration is in the sugar industry for which it has been shown that the conventional purification can be partially or completely replaced by UF and NF [73]. Indeed, ceramic membranes are well adapted to the treatment of highly viscous sugar syrups for which separation of colored matter from a green syrup is a crucial step in sucrose crystallization [74,75]. In other respects, it has been reported that the pretreatment of molasses with MF ceramic membranes can be beneficial to ethanol fermentation [76].

### 6.3.3 PRODUCT RECOVERY

#### 6.3.3.1 Purification of Pharmaceuticals and Bioproducts

Membrane filtration technologies are finding applications in pharmaceuticals industry for genomics, proteomics, drugs discovery, and generally for laboratory applications in life science, with additionally the possible production of ultra pure process water. In the bioindustry, recovery and purification of products also involve membrane technologies. Although polymer membranes are

**FIGURE 6.25** Configuration of a batch system membrane plant designed for microfiltration of fermentation broth.

largely used in these sectors, the place of ceramic membranes is increasing due to a better capability to be efficiently cleaned and sterilized. In particular, the new generation of microporous ceramic membranes able to work in the nanofiltration domain (see Section 6.4.1.1) is of great interest to extend current applications. The use of ceramic membranes in biotechnology was reviewed some years ago [69] showing that this sector was primarily interested by the microfiltration of fermentation broth to separate the yeast cells or cell fragments. Today the separation of microorganisms is still of interest and microfiltration is becoming more common compared to centrifugation, especially when it is used as cell separator in continuous fermentation or biological wastewater treatment. One problem is that during the filtration of cells a filter cake is formed on the membrane surface that reduces permeate flow. This is an example where back flushing has been successfully used to push the filter cake off the membrane surface back into the feed stream [77]. More recently an original idea was proposed for the same application, consisting of the implementation of a pump to withdraw permeate at a constant rate [78]. The advantage of a permeate pump compared with using a valve on the permeate side is the easiness to control the permeate flux and by the way the connective transport of material toward the membrane, and thus preventing filter cake formation. Process monitoring can be made by controlling the increase in transmembrane pressure, which can be used in turn as an indication of filter cake formation (i.e., the occurrence of critical flux for the membrane) showing when the membrane has to be cleaned [79]. A schematic representation of what could be a batch system process combining controlled permeate flux with sequential back flushing for membrane cleaning is shown in Figure 6.25.

Next to microfiltration, the commercial availability of ultrafiltration ceramic membranes with well-defined cut-off characteristics allowed the development of membrane processes dedicated to the separation of proteins and enzymes, not only in biotechnology but also in more established industries like dairy [62], fish meal transformation [80], etc. The central problem to protein separation is the adsorption of proteins on the membrane surface and even inside the porosity for molecular weight fractions smaller than pore sizes. This adsorption phenomenon results in most cases in a significant flux decline responsible for intensive cleaning operations impeding the economical feasibility of such processes. The chemical modification of membrane surface has been studied as a way of improving the separation of proteins either by generating specific interaction between the surface and proteins to be recovered or by preventing adsorption to promote a purely size separation effect [81]. An other way is to select membrane materials with a weak tendency to protein adsorption. For example, silicon carbide membrane could be very promising for protein filtration so far as a very low protein adsorption has been evidenced for this membrane material [82]. For the future, interesting developments are expected from the utilization of hybrid organic–inorganic membranes for the separation of molecules of biological or pharmaceutical interest. Chiral-selective membranes [83] or supramolecular chemistry-based membranes for biomimetic transport [84] are studied on the laboratory scale with the aim to separate a number of valuable molecules from reaction mixtures or natural extracts. These studies are attendant to the research on filtration and separation microdevices, which have high development potential in pharmaceuticals and bio-industry.

### 6.3.3.2 Products Manufacturing and Recycling in Various Industries

Separation of manufactured solids from process liquids and recycling of these liquids (water or organic solvents) is an interesting way to valorize by-products and to minimize the production of liquid effluents in a number of industries. Microfiltration ceramic membranes have been already used for the recovery of particles in the ceramic industry and in drilling operations, of pigments in paint and ink industries, and have potential applications in a wide variety of liquid–solid separation

processes. Due to the high inlet cross-flow velocity used in microfiltration, most of these particle suspensions have a strong abrasive effect on the membrane that justifies the use of ceramic membranes with good hardness properties, e.g.,  $\alpha$ -alumina or silicon carbide. The rheological behavior of particle suspensions under shear stress and the formation of a filtration cake are the two main problems, which must be addressed in these applications [85,86]. Cake formation depends not only on applied hydrodynamics in the module, in particular, the shear rate, but also on the interaction between particles depending on several parameters (pH, zeta potential, presence of surfactants or coagulants, etc.). According to Ref. [85], it is likely that cakes formed under cross-flow conditions are more compact than those formed under dead-end or stagnant conditions. This may explain the low permeate flow encountered in microfiltration of particulate suspensions when the chemistry of these suspensions as well as the applied hydrodynamics are not correctly monitored. Coupling with techniques like flotation can help the microfiltration process in solid-liquid separation [87].

Another important application domain for ceramic microfiltration membranes is the recovery of waste oils from industrial wastewater streams or the cleaning of used mineral oils. For example, to prevent formation of higher soot and ash accrument compared to the utilization of original fuel oil, the cleaning of waste oils used as a substitute for fuel oil can be upgraded using microfiltration [88]. In regard to mineral oil regeneration, successful regeneration treatments have been achieved with ceramic ultrafiltration membranes. Moreover, it has been shown that mixing of supercritical CO<sub>2</sub> with oil before the filtration process allows for a significant improvement of permeate flux by reducing oil viscosity [89,90]. Microfiltration can also extend the lifetime of cleaning baths in metal surface treatment or of lubricating fluids in machining industry. These fluids contain dirt particles as well as oil and detergents that must be separated and recycled, while the concentration must be adjusted at the correct level in order to be directly reused in the cleaning or machining process. Here also ceramic membranes offer better durability compared with their polymeric counterpart, because of the presence of abrasive particles and aggressive components. Separation of oil/water suspension using cross-flow filtration is another domain of application for ceramic membranes [91]. Ordinarily, ceramic microfiltration membranes with pore sizes close to 0.2  $\mu\text{m}$  are used for demulsification [92] and product recovery [93]. As for the other applications, there is a flux decline with time and backflushing is necessary to reduce the formation of the gel polarization layer and membrane fouling. The use of hydrophilic membranes is preferred to hydrophobic membranes for which oil is easily wetted on the hydrophobic membrane surface and induces more fouling of the membrane. Moreover, the operating pressure must be lower than capillary pressure to avoid the contamination of permeate with oil.

As a conclusion to the aforementioned current applications of ceramic membranes, a considerable change is under way for the utilization of these technologies in industry, in particular, for waste treatment and product recovery. In order to adapt to environmental regulation and to look for a sustainable economy, the tendency is to develop long-lasting solutions for clean and efficient industrial production processes. Actually, splitting between manufacturing and treatment of end-of-pipe effluents before disposal or simple discharge in the rivers or in the sea, even if these effluents are reputed to be non toxic, is expensive and not totally satisfactory on an environmental point of view. The reclamation of by-products and process fluids is one of the ways being currently explored to improve the productivity and to lower the environmental impact of industrial activities. Membrane processes have been identified as one of the suitable technologies for the development of sustainable processes in which product manufacturing and recycling are combined, thus avoiding the discharge of large quantity of wastes. Section 6.4 describes a number of new membrane processes that modify the current status of ceramic membrane technologies. Most often, they are based on new ceramic membrane prototypes not totally tested out at an industrial scale.

## 6.4 RECENT DEVELOPMENTS AND PROSPECTS

A number of new applications are likely to come in the near future for ceramic membranes, in particular the expected short-term developments for ceramic nanofilters and ceramic membrane contactors applied to liquid treatment, including biological membrane reactors. Gas and vapor separations with ceramic membranes seem to be more distant applications, although microporous silica and zeolite membrane modules are currently in operation in pervaporation or vapor separation processes. High-temperature catalytic membrane reactors (CMRs) constitute a more prospective field of investigation with high potential applications in the chemical and petrochemical industry, in particular, for producing hydrogen from fossil fuels. Most of these developments should be based on new membrane materials exhibiting either carefully controlled pore sizes down to the nanoporous range or dense crystalline structures with ion-conducting properties. Moreover, in most of these new applications, the membranes should have to withstand harsh working environment like corrosive chemical fluids and high process temperatures.

### 6.4.1 FILTRATION AND SEPARATION IN LIQUID MEDIA

#### 6.4.1.1 Nanofiltration with Ceramic Membranes

As the newest development of the liquid filtration family, nanofiltration (NF) is capable of retaining small molecules from 200 to 1000 Da, and multivalent ions. The main current applications of NF polymeric membranes are dealing with the production of drinking and process water, the sulphate removal of seawater or the desalination of cheese whey. Ceramic nanofilters were

commercialized recently and operate in a cut-off domain 500–2000 Da, higher than for polymeric NF membranes [94]. Up to now, several application areas have been identified in which the utilization of ceramic NF membranes is highly suitable, for example, when liquid media contain organic solvents. However, depending on solvent polarity and due to ceramic hydrophilicity, filtration and separation of organic solvents with ceramic nanofilters is not an easy operation. Works from the literature have shown that membrane flux is drastically decreased with apolar solvents compared to water or alcohols in the case of ceramic oxide nanofilters [23]. On the basis of these results, surface-modified ceramic membranes have been recently described, in which the wet ability was changed from hydrophilic to hydrophobic with the aim to develop membranes well adapted to apolar organic solvents [95].

Other relevant examples of application for ceramic nanofilters were recently reported [96]. The first separation problem in which ceramic NF membranes are likely to compete with polymeric membranes is the concentration of pharmaceutical components in their reaction solvents. Ceramic nanofilters are also of interest in the agro-food industry for separation processes working at relatively high temperature and or in the presence of organic solvents. Another potential application is in the production of chemically modified sugars in which the *N*-methyl-pyrrolidone (NMP), used as the solvent for the reaction, needs to be removed from the product (minimum molecular weight about 1000 Da) down to 0.1%. In this case, diafiltration with a ceramic NF membrane has shown to be an efficient way of decreasing the NMP content down to the intended low NMP residual concentration. Also in the sugar industry, where micro- and ultrafiltration are already used for pretreatment of sugar juices, a potential application of ceramic nanofilters is the purification of clarified or pre-evaporated juices as an alternative to ion exchange resins. Typical fluid parameters (sugar concentration from 7 to 25 Brix, feed temperature of 90°C–100°C) justify the use of ceramic membranes instead of polymer membranes. Ceramic nanofilters have also been tested for the treatment of textile wastewater, of alkaline solution from bottle washing machines, or of pickling bath solutions from the metal-working industry [97]. For the future, new applications are expected in the chemical industry. A typical problem for which ceramic NF membranes could afford a viable solution is the recovery of homogeneous catalysts from nonaqueous solvents, in particular the recuperation of transition metal complexes [95].

#### 6.4.1.2 Membrane Contactors and Distributors

There are many operations in chemistry, biotechnology, or agro-industry in which membranes can serve as contactors and distributors between two phases: liquid/liquid or gas/liquid. The high contact surface displayed by the porosity of a membrane allows highly efficient exchanges between hydrophilic phases and gaseous or lyophobic phases. Moreover a narrow distribution of pore sizes allows very sharp process control in a number of applications like emulsification, micromixing, osmotic distillation, perstraction, ozonation, or oxygenation [98–101]. All these technologies can be equally developed with polymer or ceramic membranes, although the very well-defined porosity and the extended range of operating conditions for ceramic porous materials are of specific interest in many applications of membrane contactors and distributors.

Membrane emulsification is a relatively new technique with specific advantages (simplicity, potentially less energy demands, less surfactant, and narrow droplet-size distributions) compared to conventional emulsification techniques [102]. Depending on the membrane hydrophilicity/hydrophobicity and the composition of the two liquid phases, O/W, W/O, or MW emulsions may be produced. Most often used, O/W membrane emulsification consists of the pressurization of oil (dispersed phase) through membrane pores at high pressure (Figure 6.26). The oil jet flows formed in the circulating continuous phase are

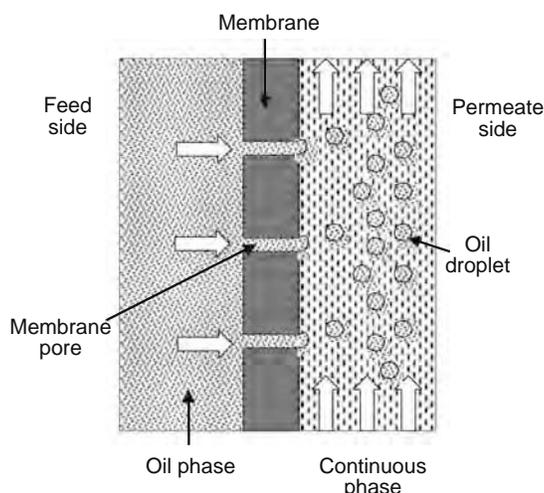

FIGURE 6.26 Schematic representation of cross-flow membrane emulsification.

ruptured to calibrated droplets by action of shearing force. The pore size of membrane and pressure determine the droplet size of the emulsion at the same time. It has been established that for producing O/W emulsions with droplet sizes of about 1  $\mu\text{m}$ , membranes must exhibit a nominal pore size in the range 0.2–0.8  $\mu\text{m}$  with a limitation on applied transmembrane pressure. Therefore there is a strong economical limitation because of the low membrane fluxes (a few liters per hour and square meter) expected for such operating conditions. Recently, a two-stage ceramic membrane jet flow emulsification process has been proposed able to solve the paradox between the flux and droplet size [103]. In this process, a coarse emulsion of oil droplets (size  $\sim 50 \mu\text{m}$ ) is prepared on the first membrane stage at a pressure allowing a high membrane flux ( $J > 100 \text{ L/m}^2 \text{ h}$ ). Droplets result from thin streamlines of oil formed under jet flow, which are then ruptured by action of shearing force along the membrane. Then the coarse emulsion is pressurized on the second membrane stage (pore size  $> 1 \mu\text{m}$ ). Normally, at low pressure when oil droplets are larger than pore size, the oil phase is separated from water (see Section 6.3.3.2). In the present case, due to the combination of high pressure (250 kPa) and high membrane flux ( $J \gg 100 \text{ L/m}^2 \text{ h}$ ), the droplets are pressured through the membrane pores resulting in the formation of a monodispersed emulsion with micron size droplets. In fact, the second stage looks like a multiple emulsification process.

A wide range of application areas of membrane emulsification have been developed from simple food spreads to the manufacture of complex colloidal assemblies [99]. This method affords the production of a variety of structured particulate materials by means of sequential secondary reactions/processes in the emulsified droplets, such as polymerization, gelation, evaporation, freeze-drying, solidification, crystallization, and droplet swelling. For example, nonaqueous droplets containing a monomer mixture can be converted to polymer microspheres by heat-induced polymerization. Besides, the oil droplets can be made up of a high melting-point oil and can be transformed into solid particles by cooling. Similarly the hot droplets of a metal solder can be solidified to produce fine solder powder. Derived from membrane emulsification, membrane micro-mixing and dispersion/precipitation have been described as an innovative method to produce unagglomerated inorganic spherical nanoparticles with a narrow size distribution [104]. In this last example, barium sulphate particles (widely used in pigment, printing ink and medicine) with diameters in the range of sub-200 nm have been produced using a low-energy consumption method developed from the combination of direct precipitation method with an inorganic membrane dispersion technology.

Another important application area for membrane contactors consists of gas–liquid absorption or liquid–liquid extraction (LLE) processes. For example, ozonation is applied in several environmental engineering processes, such as disinfection of drinking water, oxidation of micropollutants, or removal of odor, color, and particles. Operational disadvantages of conventional ozonation processes are an inefficient control of mass transfer because of independent contact between gas and liquid phases resulting in flooding, uploading, emulsion, and foaming. The utilization of membranes for ozonation of liquids affords decisive advantages over conventional processes: (1) much higher interfacial area per volume; (2) higher mass transfer coefficient; (3) easy recycling of  $\text{O}_2/\text{O}_3$  gas mixture back to ozone generator; (4) easily control of ozone gas concentration at liquid–gas interface [105]. Ceramic membranes are superior to polymer ones in this application because of the much better resistance of ceramic material to ozone, a strong oxidant agent. However, to be competitive, ceramic membranes that are hydrophilic by nature, should exhibit a stable hydrophobic surface in this case, to provide high gas transfer rates [106]. Membrane contactors can be also proposed as an alternative to conventional LLE, with the implementation of techniques such as membrane extraction and in a less extent membrane pertraction. These techniques can avoid specific problems of LLE, e.g., solvent loss, emulsion formation, and complex phenomena resulting from the physicochemical instability of the organic–aqueous phase interface [107]. Two other techniques based on a membrane contactor design should be mentioned: (i) osmotic evaporation, which is based on a water vapor pressure difference induced by the difference in the water activity of two aqueous solutions, separated by a porous hydrophobic membrane [108], (ii) membrane distillation in which transport depends upon the vapor pressure gradient caused by the difference in temperature across an hydrophobic membrane [109]. Nevertheless, the utilization of ceramic membranes as contactors for all these applications will require the development of ceramic membranes with a stable hydrophobic surface and a narrow pore size distribution [110].

## 6.4.2 GAS AND VAPOR SEPARATION

### 6.4.2.1 Gas Separation

In most of the literature, gas separation using ceramic membranes, including carbon membranes, is considered to be very promising. However, there are still economical and technical limitations to the industrial development of gas separation processes based on inorganic membranes. Most often, the synthesis of ceramic gas separation membranes is a tricky and not reproducible process with the presence of residual defects and pinholes in the membrane top-layers, which induces high production costs. Accordingly, most of R&D projects in this area are still focused on the membrane as a material and much less on the membrane process, so that insufficient data are available on the real possibility of developing large-scale applications. Anyway, the last decade has seen significant progress in microporous and dense ceramic membranes exhibiting fascinating gas permeation and separation properties [7]. These inorganic membranes able to carry out gas separation at elevated temperatures are potentially useful in emerging areas such as catalytic reactors for gas oxidation and hydrogenation reactions, natural gas or

biogas processing, power generation using fuel cells, and hydrogen production from different fuel sources. There are three main categories of porous inorganic membranes currently investigated for gas molecular separation [111], e.g., silica-based, zeolite, and carbon membranes, while dense gas separation membranes refer to polycrystalline materials in which gas molecules permeate as ionic species [25]. Hybrid organic–inorganic membranes have also been mentioned to having potential application in gas processing, in particular, for natural gas processing and the production of high-density hydrogen without any impurities [112].

Since the very early publications dealing with gas separation using inorganic membranes, a large part of the studies have been based on silica and its derived materials. Silica microporous membranes have been extensively studied and most often synthesized by the solgel process [113–115]. These membranes are quite stable when used in dry atmosphere, but gas permeance decreases drastically in humid conditions due to silica network rearrangement and subsequent formation of a more tight structure. Silica-based inorganic membranes selectively separate hydrogen from other gases, but permselectivity between similar sized molecules, such as oxygen and nitrogen, is not sufficient [116]. Different ways have been explored for increasing performance of silica membranes, for example, by improving the quality of support (smaller pores and smoother surface) as well as coating of silica films under clean-room conditions [116,117], by the templating solgel approach [118–122], or by CVD-based preparation methods [14,15]. The hydrophobic modification of pore surface has also been used to prevent interaction with water [123].

In other respects, we can consider zeolite membranes as pertaining to the ceramic material category. Indeed zeolites are classified for the most part as microporous, crystalline silico–aluminate structures with different aluminum/silicon ratios. Thus, the chemical compositions are close to those of ceramic oxide membranes, in particular of microporous silica and alumina membranes. On the other hand, zeolites are crystalline materials and they have a structural porosity very different from microporous amorphous silica [124]. Zeolite membranes are well adapted to the separation of gases, in particular  $H_2$  from hydrocarbons, but these membranes are not very selective for the separation of mixtures of noncondensable gases.

Besides the aforementioned crystalline or amorphous microporous ceramic membranes, molecular sieve carbon (MSC) membranes have been identified as very promising candidates for gas separations [125,126]. Ordinarily these membranes are prepared by pyrolyzing thermosetting polymers and exhibit pore diameters of 3–5 Å. They have ideal separation factors for various combinations of gases ranging from 4 to greater than 1000. Carbon membranes can be prepared as supported and unsupported membranes. They have been produced under different membrane geometries: flat or tube for the former, and flat, hollow fiber, or capillary for the latter. Carbon membranes have strong application potential for hydrogen recovering from waste gases or for alkenes/alkanes separation. However, MSC membranes are very brittle and fragile, requiring careful handling. When they are operated with non-purified gases, they require a pre-purifier step for removing traces of strongly adsorbing vapors, which can clog up the pores. This problem may be avoided by operating at high temperature, but carbon membranes are not stable at an elevated temperature under oxygen or steam atmospheres.

The last category of inorganic membranes used for gas separation is constituted of dense materials including metals and ceramics [127].

Metallic membranes are not considered as belonging to ceramic membranes so that its related applications will not be discussed in detail. Ordinarily these membranes are mainly made up of Pd-based alloys and are used for hydrogen separation and hydrogenation or dehydrogenation reaction control [128–130]. Metallic membranes exhibit high hydrogen separation selectivity but most of the used metal alloys suffer from instability and must be used in controlled atmosphere and temperature range. Many basic research projects on this topic are still in progress [131,132]. However, metallic membranes have been already used at an industrial scale, for example, in semiconductor industry to produce ultra-high purity hydrogen [133].

The second class of dense membranes thoroughly investigated for gas separation involves ceramic oxide materials exhibiting high solid-state diffusion rates of oxygen ions and protons at high temperature [25,134]. At this time, the development of inorganic proton-conductive membranes able to work at intermediate and high temperatures, in absence of water, is very challenging in many industrial sectors such as hydrogen separation in gas processing, hydrogen or direct methanol fuel cells, electrochemical treatment of aqueous solutions, electrosynthesis, or advanced ceramic membrane electrolyzers for hydrogen production [135,136].

For comparison, the characteristics, permeation, and selectivity of these different categories of gas separation membranes are summarized in Table 6.2. By nature, mesoporous membranes exhibit high permeation flux, but low selectivity based on the Knudsen diffusion mechanism. On the contrary, permeate flux for microporous membranes is at one order of magnitude lower with higher separation selectivity than for the mesoporous membranes, but which strongly depends on temperature [137]. In other respects, for defect-free dense ion-conducting membranes the selectivity is infinite as only oxygen ions or protons can migrate through the crystalline structure [25].

#### 6.4.2.2 Pervaporation and Vapor Permeation

Pervaporation and vapor permeation are typical membrane processes with high application potential in chemical industry due to their high efficiency in the separation or the dehydration of organic solvents. Developed initially with organo-polymeric

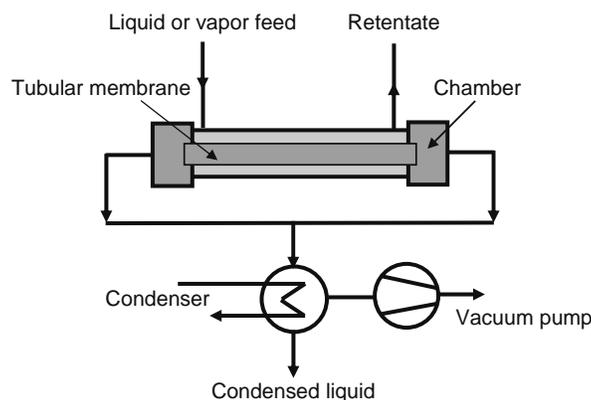

**TABLE 6.2**  
**Gas Separation Characteristics of Inorganic Membranes**

Membrane Type	Pore Size Range	Membrane Thickness Range	Permeation Range (mol/m <sup>2</sup> s Pa)	Separation Mechanism (Gas/Gas Selectivity <sup>a</sup> )
Mesoporous ceramics	~4 nm	1–5 μm	10 <sup>-5</sup> to 10 <sup>-6</sup>	Knudsen diffusion (<10)
Mesoporous glass	~4 nm	5–300 μm	10 <sup>-6</sup> to 10 <sup>-9</sup>	Knudsen diffusion (<10)
Microporous oxides	<1 nm	0.1–1 μm	10 <sup>-7</sup> to 10 <sup>-8</sup>	Temperature activated transport (<200)
Microporous carbons	~0.5 nm	1–10 μm	10 <sup>-7</sup> to 10 <sup>-8</sup>	Microsieving <200
Zeolites	~0.5 nm	1–5 μm	10 <sup>-6</sup> to 10 <sup>-7</sup>	Surface diffusion + temperature activated transport (<100)
Ion conductive ceramics	Dense	10 μm to 5 mm	10 <sup>-9</sup>	Ionic transport (infinite)

<sup>a</sup> In the case of H<sub>2</sub>, the separation selectivity is one to two order of magnitude larger than the figures listed in this column due to the high diffusivity of this gas compared to other gases.

membranes, the main limitation to industrial application is still the lack of membranes being selective and chemically resistant in an organic solvent environment. In comparison, the high thermal and mechanical stability as well as the excellent chemical resistance of inorganic membranes make them well adapted to working conditions of chemical processes. The general principle of PV or VP separation is shown in Figure 6.27. In PV processes the feed is a liquid, while vapor exits the membrane on permeate side. VP has certain similarities with PV but uses gaseous components on the feed side of the membrane. However, some differences between these two processes have to be mentioned with respect to operating conditions [138]. First, vapor permeation fluxes depend strongly on feed pressure whereas pervaporation fluxes are independent. Then, heat transfer within the membrane is more a consideration for pervaporation because of vaporization phenomenon. Finally, concentration polarization in the feed is more likely to occur during pervaporation because of slower diffusion in the liquid phase than in the vapor phase. PV and VP inorganic membranes are implemented most often as tubular modules. Microporous silica and zeolites have been identified as suitable membrane materials for PV and VP applications.

Currently, pervaporation with zeolite membranes is the most advanced technology at an industrial scale [138]. The growing interest for zeolite-based pervaporation process lies not only in the excellent chemical resistance of these membranes, but also in the high separation selectivity and high permeate fluxes compared to organo-polymeric membranes. The current large-scale commercial application of zeolite membranes is dehydrating alcohols and other organic compounds for solvent recovery. A typical example is the zeolite membrane pervaporation plant built by Mitsui Engineering & Shipbuilding Company, Japan [139]. It produces 530 L/h of dehydrated alcohol (0.2% residual water content) from feed alcohol containing 10% water, with separation factors as high as 10,000. Recently this company has implemented in Europe, 6 large module vapor permeation plant for dehydration of biomass ethanol at 135°C [140]. Each module is composed of 550 zeolite NaA membrane elements and is able to produce 5000 L of dehydrated ethanol per day. The NaA zeolite membrane has been demonstrated to be very effective for the separation of water/organic liquid mixtures, while the NaY zeolite membrane is more adapted to the separation of organic binary mixtures [141]. The permeation and selectivity characteristics of these membranes are reported on Table 6.3. One can see that membrane performance may be very different depending on

**FIGURE 6.27** General working principle of a pervaporation or vapor permeation module equipped with tubular ceramic membrane elements.

**TABLE 6.3**  
**Performance of NaA and NaY Zeolite Membranes for Component Separation in Respective Water/Organic and Binary Organic Mixtures**

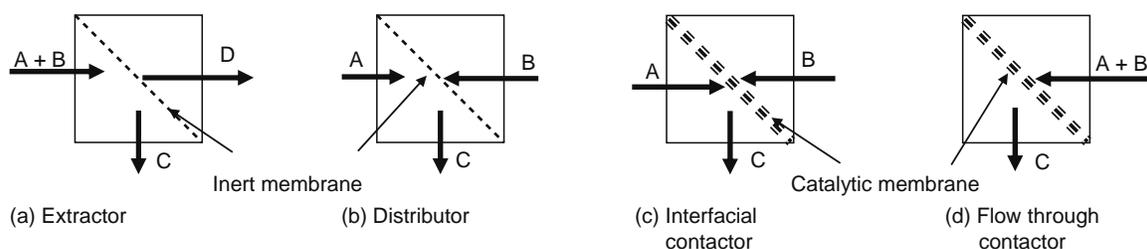

Zeolite	Feed Solution (A/B) (wt% of A)	Temperature (°C)	Separation Factor (A/B)	Flux (kg/m <sup>2</sup> h)
NaA	Water/methanol [10]	50	2,100	0.57
		105	5,700	3.50
	Water/ethanol [10]	75	10,000	2.15

the nature of the binary organic mixtures. In fact each zeolite membrane is revealed to be efficient, only in a limited number of applications. This explains the ongoing important research works devoted to zeolite membranes to cover all potential applications. Small-, medium-, and large-pore zeolites such as Mordenite, ZSM5, Silicalite-1, or SAPO-34, with an hydrophilic or hydrophobic behavior, are currently investigated as pervaporation or vapor permeation membranes. Today more than 14 zeolite structures have been prepared as membranes [138].

Microporous membranes based on hydrophilic silica have also been developed [142] in view of industrial application for the dewatering of organic solvents. Silica membranes are less selective than zeolite membranes but they exhibit higher permeate fluxes. For example, in the case of ethanol dewatering at 80°C, the required membrane area for a silica membrane can be 10 times lower than for the equivalent polymeric membrane. As for zeolite membranes, the price of silica membranes dominates the investment cost and dampens industrial developments. A recent study on PV silica membranes pointed out the possibility of substantial cost savings by designing new modules and optimizing module arrangements [143]. It has been shown that conventional modules need up to 50% more membrane surface than a new isothermal module design [144] developed by Sulzer Chemtech. In the same way operating costs are reduced by 20% with optimized working conditions for module setup. Other materials are currently investigated on the laboratory scale to extend the categories of available PV or VP membranes. For that purpose, a better thermochemical stability is expected from binary oxide systems [145,146]. Hydrophobic PV membranes have been also studied for separating organic compounds from organic/water mixtures having low organic concentration [147].

### 6.4.3 CATALYTIC MEMBRANE REACTORS

Many research efforts have been devoted to the application of inorganic membranes in catalytic reactors on the basis that all types of homogeneous or heterogeneous catalytic reactions can be in principle assisted by membranes. The concept of combining reaction and separation is being explored in various configurations, which can be classified into three groups related to the role of the membrane in the process [148]. In a chemical reaction involving two reactants A and B, yielding one or two products C and D, the three different roles of the membrane for improving selectivity and conversion are schematized in Figure 6.28. Note that for extractors and distributors, inert membranes are used, while membranes are catalytically active for contactors. These designs are common to the three main types of membrane reactors investigated to date and involving ceramic membranes, i.e., gas-liquid-solid, biocatalytic, or high-temperature reactors. In the future, it is likely that new reactor concepts

**FIGURE 6.28** Roles of the membrane in membrane reactors. (a) Extractor: the removal of product(s) increases the reaction conversion by shifting the reaction equilibrium; (b) distributor: the controlled addition of reactant(s) limits side reactions; (c) and (d) active contactors: the controlled diffusion of reactant(s) to the catalytic membrane can lead to an engineered catalytic zone.

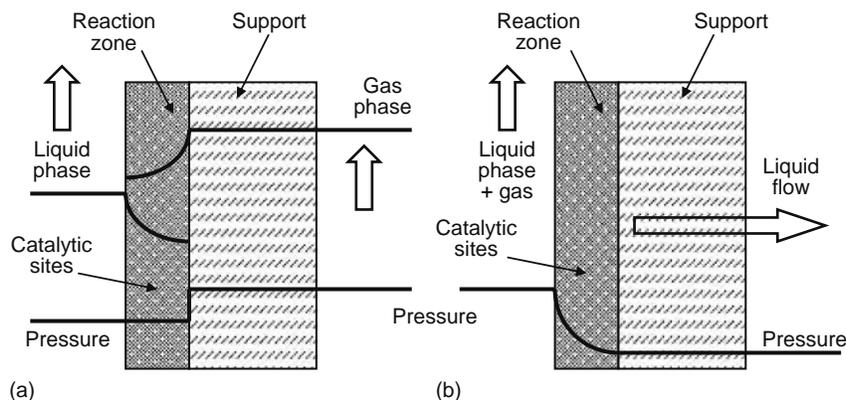

will extend the list of membrane reactor concepts such as membrane-mediated reactions in supercritical fluids [149] or photocatalytic assisted membranes for the treatment of water and wastewater [150].

### 6.4.3.1 Chemical Reactors Based on Gas–Liquid–Solid Membrane Contactors

Ceramic catalytically active membranes have high potential for supporting gas–liquid reactions [151–153]. This non-separative prospective application does not require a permselectiveness of the membrane. In fact the role of the porous ceramic membrane is to provide a well-defined contact region among the gas phase, the liquid phase, and the catalytic active phase deposited on the membrane. In this configuration the membrane material itself may exhibit intrinsic catalytic activity. As for simple membrane contactors, an additional benefit of using such reactor configuration is the high interfacial area per volume due the high specific surface area developed in the porous structure of the membrane.

Two reactor concepts may be distinguished [153], which are schematized on Figure 6.29. One consists of the gas phase and the liquid phase flowing, respectively, on each side of the membrane (Figure 6.29a). In this case one reactant is dissolved in the liquid phase, which is sucked by capillary forces into the catalytic membrane layer, getting the reactant in contact with the catalytic sites. The gaseous reactant is fed on the other side through the porous support of the membrane. As a result, a gas–liquid phase boundary establishes, which is determined by the pressure difference between the gas and the liquid side. The pressure must be controlled in order to have the phase boundary in the membrane layer where catalytic active sites are located so that the contact between the liquid reactant, the gas reactant, and the solid catalyst are optimum, enhancing overall reaction rate. The second type of reactor configuration is based on a through flow concept (Figure 6.29b). This configuration may be useful when the reaction is very fast. Contrary to the first configuration in which the limiting step was mass transport due to reactant diffusion in the liquid phase, in the second case, instead of establishing a phase boundary in the membrane, the gas reactant and the liquid phase reactant are mixed prior to be forced through the catalytic active membrane layer. Accordingly, avoiding the problem of reactant diffusion in the pores, the contact time at the catalytic sites can be varied by changing the flow rate through the membrane, so that very short contact times can be achieved.

These two concepts have been proved on a laboratory scale, mainly for hydrogenation reactions but can be transposed to many gas–liquid catalyzed reactions. Interesting potential applications have been mentioned, such as asphaltene hydrocracking or nitrate and nitrites removal from drinking water by catalytic nitrate reduction. However, the characteristics of ceramic

**FIGURE 6.29** Concepts of membrane reactor based on gas–liquid–solid ceramic membrane contactors.

membrane devoted to this application have still to be improved to significantly increase mass transfer and efficiency of these systems. For the first concept in which a gas–liquid boundary is established in the membrane, thinner ceramic membrane layers with a narrow pore size distribution should be produced, ensuring shorter diffusion paths and efficient mass transfer [152]. For the flow through concept, a homogeneous distribution and a good accessibility of catalytic sites in the membrane porosity are the main conditions for a successful process.

### 6.4.3.2 Biocatalytic Membrane Reactors

These reactors constitute a complementary and more prospective aspect to membrane bioreactors described in Section 6.3.1.2. The aim of developing such reactors is to use the catalytic action of enzymes for large-scale production in agro-food or pharmaceutical industries [154]. Possible applications in biomedical or environmental sectors have also been mentioned [155]. The interest of using the catalytic action of enzymes is that they are extremely efficient and selective. In general enzymes demonstrate higher reaction rates, milder reaction conditions, and greater stereospecificity compared to chemical catalysts. Thus, this category of membrane reactors offers the advantage of environmental-friendly technologies.

Here also ceramic membranes may have a number of specific advantages over polymeric membranes. Porous ceramics exhibit a non-deformable porous structure, which resists to microbiological attacks and can withstand different reaction media (aqueous, organic, and supercritical fluids). Moreover ceramic porous media can be reused after elimination of aged biological catalysts followed by a thorough reactor cleaning and sterilization with chemicals and steam. Different configurations have been proposed for these enzymatic membrane reactors. Two ways have been effectively tested for coupling enzymatic activity with membranes: the one in which the biocatalytic medium is flushed along the membrane module (Figure 6.30a) and the other with enzymes fixed or entrapped in the porous medium (Figure 6.30b). In the former case, the membrane is used to retain the enzymes and the substrate(s), while allowing the products to pass through. In other respects, when the enzymes are immobilized in the porosity of the membrane, pores containing the enzymes can be considered as many of microreactors in which much higher conversion and selectivity can be achieved than in a batch reactor [154]. Actually in the microreactor concept, an outstanding property is the extremely large surface-to-volume ratio inducing a minimization of mass transfer path and a substantial increase of transfer rate.

The use of enzymatic membrane reactors on an industrial scale is not yet fully established, however, some interesting reactor designs have been proposed in the literature. One of them combines a ceramic membrane as the support for enzymes with supercritical CO<sub>2</sub> as the reaction solvent [156]. The objective of this work was to obtain high-value products in the food and health industry from enzymatic modification of fats and oils. For that, an enzyme (a lipase) is chemically immobilized in a proteinic membrane top-layer supported on a macroporous ceramic element. The enzymatic reactor works according to the flow through concept, the role of supercritical CO<sub>2</sub> being the fluidization of a viscous mixture of substrates (castor oil and methyl oleate) to facilitate mass transfer across the membrane top-layer and diffusion path to enzymatic catalytic sites. This reactor concept is very promising as it showed a good stability for enzyme activity with pressure, temperature, and time under supercritical condition as well as an enhanced conversion rate due to the supercritical medium. More generally biocatalytic membrane reactors are studied for agro-food, pharmaceutical, biomedical industries, and even for wastewater treatment [155]. Except for biomedical applications dealing with artificial organs, all the other sectors could benefit from enzymatic reactors equipped with ceramic membrane elements. In the agro-food sector enzymatic membrane reactors could be used for: reducing

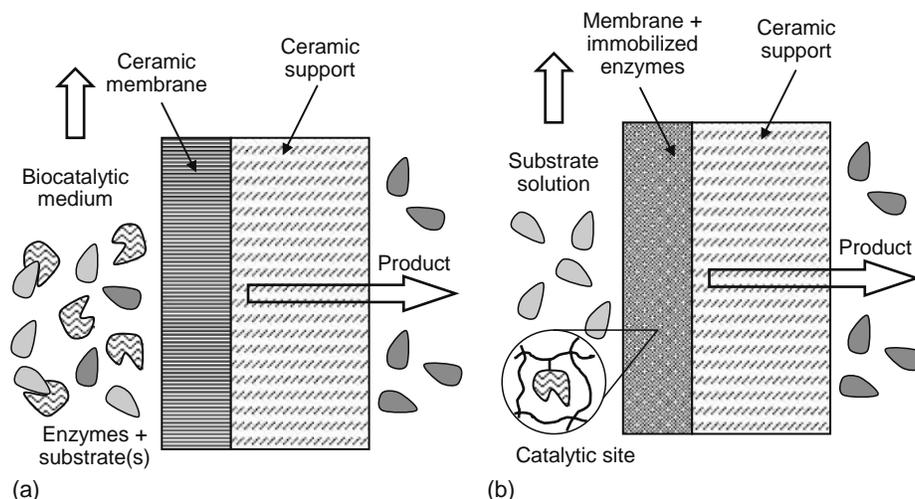

FIGURE 6.30 Concepts of biocatalytic membrane reactors with (a) non-immobilized or (b) immobilized enzymes.

the viscosity of juices by hydrolyzing pectins, reducing the lactose content in milk and whey by its conversion into digestible sugar, the treatment of musts and wines by the conversion of polyphenolic compounds and anthocyanes, and the removal of peroxides from dairy products. In the pharmaceuticals sector, these reactors could be implemented for the production of amino acids, antibiotics, anti-inflammatories, anti-cancer drugs, vitamins, etc. For water and wastewater treatment, biocatalytic membrane reactors are of interest for converting highly hazardous contaminants, which cannot be destroyed or removed by conventional treatments.

### 6.4.3.3 High-Temperature Catalytic Membrane Reactors

Catalytic membrane reactors working at high temperature are certainly the most innovative and challenging developments expected for ceramic membranes in the near future [157,158]. These reactors offer the possibility of combining reaction and separation at high temperature to overcome the equilibrium limitations experienced in conventional reactor configurations. A number of industrial applications have been identified in chemical industries, which include hydrogenation, dehydrogenation, oxidation, and catalytic decomposition processes. Many examples of the potential utilization of the different categories of inorganic membranes in CMRs can be found in the literature [159–171]. More recently, the new power generation technologies based on hydrogen or syngas production arose as a very promising industrial activity in which ceramic membrane reactors can be considered as a key technology. However, few of these processes have passed the laboratory scale, although some important R&D projects, carried out by industrial consortia, were mentioned recently [19].

In fact there has been a shift of interest for CMRs during the last decade [172]. In the early 1990s, dehydrogenation of styrene and butane with the shift reaction equilibrium was a major concern in the studies. From 1994–2000 interest was mainly focused on methane processing with the aim of gas-to-liquid fuel transformation or hydrogen production. At the moment, industrials involved in new hydrogen or syngas-based power technologies are seeking to develop reliable CMRs for the partial oxidation or direct coupling of methane, natural gas, or biogas. Many research efforts are devoted to these technologies including the investigation of new membrane materials, the design of innovative reactor systems, and the coupling with other technologies like solid oxide fuel cells or energy cogeneration systems. Actually the development of CMRs working at high temperature is still constrained at the one hand by the cost of these systems, which should be less than 1000 €/m<sup>2</sup> for installed membranes, on the other hand by the need for more selective and reliable ceramic membranes, able to withstand high temperature and harsh operating conditions. Three main designs (Figure 6.31) have been proposed for these membrane-reaction systems, going from a simple and reliable implementation configuration to more sophisticated, but risky configurations. These three configurations consist of (i) separate membrane and catalyst; (ii) catalyst dispersed in the membrane; and (iii) inherently catalytic membrane material. It is apparent that the failure of the membrane in the second and third categories will necessitate complete replacement of the entire membrane reactor system, while catalyst or membrane failure may be treated independently in the first category.

Inorganic membranes exhibiting either dense structures or macro-, meso-, and microporous structures can be implemented in CMR devices. At this time, the former category includes dense metal membranes for hydrogen extraction as well as ion and mixed ion-electron conducting ceramic membranes active in the selective transport of oxygen ions and protons at high temperature. Originally dense metal membranes based on Pd and Pd-alloys have been developed for shifting equilibrium in dehydrogenation reactions. In the case of oxygen-ion conducting ceramic membranes, the partial oxidation of methane has been the most studied reaction involving two types of membrane reactors: pressure driven devices using mixed ions-electrons conducting membranes [160] or electrically driven devices using membrane electrolytes made of purely ion-conducting metal oxides [165,166]. Oxygen transport membranes are also envisioned as a part of Integrated Gasification Combined Cycle (IGCC) systems [173] or as a way of mitigating CO<sub>2</sub> emission by enabling the recycling of a O<sub>2</sub>/CO<sub>2</sub> mixture in fuel combustion plants [174]. Proton-conductive ceramic membranes have been studied recently. This kind of membrane is designed for the transport of protons and electrons at high temperature, producing a stream of pure hydrogen suitable for use in hydrogen technologies [175]. An interesting process concept has been proposed by Praxair, Inc. and Argonne National

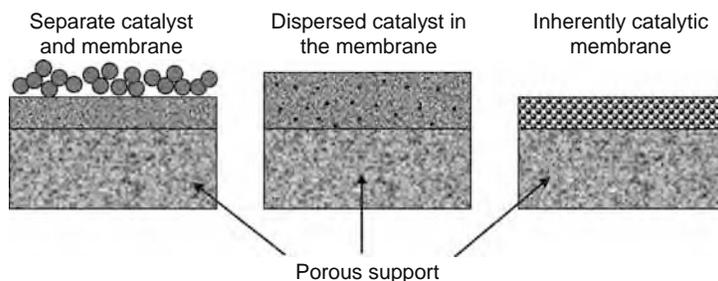

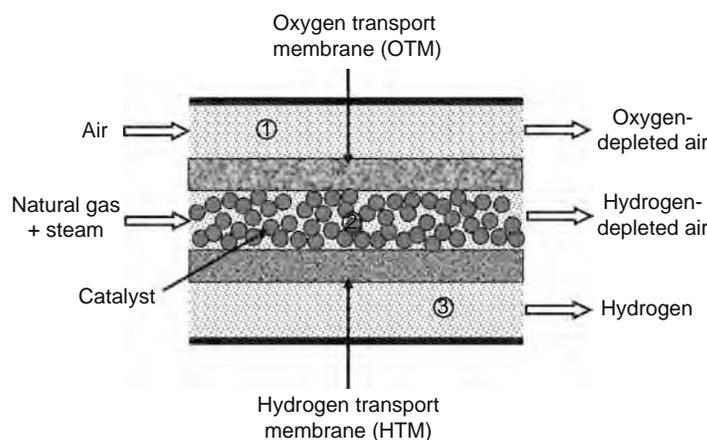

FIGURE 6.31 Different catalyst-membrane designs for implementation in catalytic membrane reactors (CMRs).

**FIGURE 6.32** Schematic diagram of an integrated distributor/extractor membrane reactor based on the combination of dense ceramic oxygen and hydrogen transport membrane for syngas production.

Laboratory combining both dense ceramic oxygen (OTM) and hydrogen (HTM) transport membranes to produce syngas and purified hydrogen from natural gas [176]. This process concept integrates various processing steps in a single distributor/extractor membrane reactor. The reactor is divided in three compartments separated by the OTM and HTM membranes (Figure 6.32). Natural gas and steam are introduced in the central reactor compartment containing a catalyst, where partial oxidation, steam reforming, and water gas shift reactions take place. Simultaneously, oxygen is distributed from the air compartment to the reactor compartment through the OTM membrane whereas the hydrogen is extracted from the reactor compartment through the HTM membrane. The development of reliable and cost-effective OTM and HTM membranes able to be implemented in this kind of reactor is very challenging for future hydrogen-based energy production.

In other respects, the role of porous ceramic membranes in CMRs must be regarded in close relation with the mode of gas transport through the membrane porous structure (see Section 6.2.2.2). The viscous flow controlled by the transmembrane pressure in macroporous ceramic membranes is well adapted to the distribution of reactive gases in a reactor. A very innovative concept has been proposed recently for oxygen distribution in partial oxidation membrane reactors [177,178], based on an infiltrated membrane system. Mesoporous ceramic membranes are more suitable for catalytic membrane contactors because of the Knudsen diffusion that promotes the contact between gas molecules and catalytic sites present on pore walls [179,180]. Finally molecular sieving, surface diffusion, or temperature-activated transport in microporous ceramic membranes can be advantageously used for selective gas extraction in reactors. These membranes can be an alternative to dense metallic membranes that do not withstand extreme operating conditions, for example, in the case of hydrogen extraction from the reaction zone in a fluidized-bed reactor specially designed for oxo-alcohol synthesis gas production [181].

## 6.5 CONCLUSION

As mentioned in this chapter, the field of membrane technology is broad and continuously expanding in many industrial sectors. It involves different aspects starting with the production of membranes with well-defined characteristics and ending with the implementation of various processes dealing with a large number of operations such as simple filtration, selective separation, solutes or solid matter concentration, fluid distribution, and even catalytic conversion or reaction control. The potential growth for worldwide membrane markets is 10%–15% a year. Even if the share of ceramic membrane-based processes is quite small compared to polymeric membranes, the continuous increase in ceramic membrane equipment sales during the last decade, estimated at €300 million in 2005, holds high promise for the future.

Since the first industrial developments in cross-flow microfiltration in early 1980s, significant progress was achieved with ceramic membranes presently, affording new products with improved permeate flux, separation selectivity, and system compactness. Effectively, monolithic and hollow fiber elements have resulted in a significant increase in membrane surface to volume ratio, closer to the compactness of polymeric membrane systems. Ceramic nanofilters are able to carry out separation on the molecular scale in liquid, gas, or vapor media. The commercial availability of inorganic membrane materials now includes nonoxide ceramics (silicon carbide or silicon nitride), zeolites, and will extend to nanophase and hybrid materials in the near future. CICMs are under development for high-temperature membrane processes that will be central to new power generation technologies (hydrogen and syngas production, solid oxide fuel cells).

The actual interest for ceramic membranes in many applications dealing with the treatment of liquids results from an increasing demand for secure and reliable membrane processes. In the food and pharmaceutical industries for which sanitary requirements are of the utmost importance, ceramic membranes afford a very good reliability in terms of cleaning and

sanitization procedures. For the treatment of liquid wastes and the regeneration of process fluids, the high resistance and the long durability of ceramic membranes are a great asset to the development of clean and efficient processes in many industries. In a general way, ceramic membranes should actively participate to the implementation of modern technologies and should be able to adapt to environmental regulation by avoiding the discharge of large quantities of wastes.

For the future, ceramic membrane technologies will extend to the treatment and the separation of gases and vapors up to elevated temperatures (800°C–900°C). Moreover, membranes and modules with new designs will diversify the role of the membranes as extractor, distributor, or contactor in biological or chemical processes. On this basis, new generation of membranes, ceramic membrane reactors arise as an innovative and challenging technology combining separation and reaction, able to overcome the equilibrium limitations experienced in conventional reactor configurations. Ceramic membranes afford specific advantages in these applications, in particular the biological inertness, the high chemical and mechanical resistance, and the ability to work at elevated temperature. Nevertheless, two difficulties have to be surpassed to allow the industrial development of these new technologies, still experienced on the laboratory scale. One is technical with the expected development of large scale and reliable membrane fabrication processes and the other is economical with the necessity to significantly decrease the production cost of these membranes.

## 7.1 INTRODUCTION

Worldwide, billions of pounds of organic solvents are used as processing tools, cleaning agents, and dispersants. Due to their specific properties, which overcome the disadvantage of costly high-pressure conditions, supercritical fluids can be proposed as alternative solvents. Supercritical carbon dioxide (SC CO<sub>2</sub>) which is low cost and nontoxic, and presents intermediate thermodynamic (density, solvent power) and transport (viscosity, diffusivity) properties between gases and liquids easily tuneable with temperature and pressure, is certainly one of the most attractive. Because of its high potentials in the fields of solid and liquid extraction, chromatography, particle formation, dyeing of yarns, and reactions, SC CO<sub>2</sub> has been largely used already in food and pharmaceutical areas. Large-scale applications incorporating other kind of compounds can also be found (such as compressed gases like propane and butane in petrol refining).

Among processes involving supercritical fluids, high-pressure reactions or separation applications with membranes have recently attracted interest. It was notably the case for operations involving barriers robust enough to support high-pressure conditions required in this field. Both kinds of membranes (i.e., organic and inorganic) are supposed to be used. In other works (presented in Section 7.7), authors have also considered supercritical fluids as attractive media for the preparation of the membranes themselves.

Inorganic membranes are very resistant and quite stable at hard-operating conditions. Several materials are available. Different membranes have been successfully tested for separations involving supercritical fluids such as tubular carbon membranes [1], tubular silica membranes [2–5], silica hollow fiber membranes [6], zeolite membranes [7–10], titanate–nafion membranes [11], polycarbonate membrane [12], nanofilter having a thin layer of ZrO<sub>2</sub>–TiO<sub>2</sub> [12], and silicalite membranes [4].

Transfer mechanisms involved in SC CO<sub>2</sub> permeation through such porous membranes can be convection (Poiseuille law), diffusion (Knudsen flow), and surface membrane interaction by adsorption, capillary condensation, etc. [11]. Mechanisms have been specifically investigated for nanofiltration and zeolite membranes. With a nanofilter presenting a pore diameter of about 1 nm, Sarrade [11] mentioned a Poiseuille flow associated with an irreversible CO<sub>2</sub> adsorption on the micropore wall. Transfer

of SC CO<sub>2</sub> through a zeolite membrane (pore diameter 0.55 nm) was based on the combination of surface diffusion (adsorption) and Knudsen diffusion [8].

Organic membranes have also been used for supercritical fluids applications in specific equipments. In that view, Damle and Koros [13] proposed a permeation equipment for high-pressure gas separation able to work with polyimide organic membrane as an example. The membrane was placed in a commercial membrane testing cell (initially dedicated to high-pressure mixed gas testing), which was previously modified to allow SC fluids permeation. In addition, Spricigo et al. [14] succeeded to perform SC CO<sub>2</sub> permeation in a dead end flow regime through a cellulose acetate reverse osmosis membrane, which was placed over a perforated metallic support; sealing was made with poly(tetrafluoroethylene) rings. Other membranes like polyamide [15] or cellulose triacetate/diacetate [16] membranes were also tested using the same apparatus.

A particular phenomenon can occur when organic membranes are in contact with SC CO<sub>2</sub>. Under high pressure, most membrane materials tend to plasticize. Specifically, the presence of the adsorbed CO<sub>2</sub> at high pressure tends to soften and dilate the membrane material [13]. This phenomenon can constitute a great limitation with the use of polymeric membranes because it induces a strong swelling of the membrane and often leads to a lack in stability of the system on the medium-long range. In what follows the different applications are examined successively.

## 7.2 SOLVENT RECOVERY

Due to its unique characteristics and physicochemical properties such as being less toxic, nonflammable, and having the extraction power tuned by temperature and pressure, SC CO<sub>2</sub> can be used as a green solvent for extraction of substances especially from solid or liquid substrates. Such extraction has been carried out on commercial scale for more than two decades and applications like decaffeination of coffee beans and black tea leaves and hops extraction are involved in large-scale processes [17]. Other extractions such as extraction of flavors, spices, and essential oils from plant materials are under investigation. An overview of published data for different materials is given in the review of Marr and Gamse [18].

As the solubility of solutes is generally low and as high pressures are often required to enhance it, large amounts of CO<sub>2</sub> are required for the extraction process. Thus, CO<sub>2</sub> regeneration for recycling use is essential to make the process economically viable.

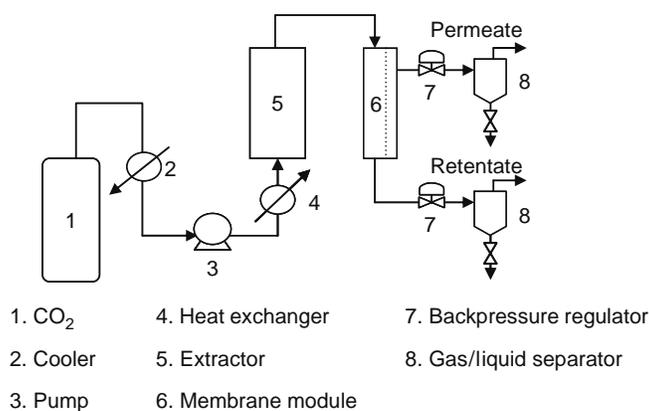

As supercritical fluids solvent power depends on pressure and temperature, solute and supercritical solvent can be separated by acting on these parameters. In addition to the extraction step, a complete process typically includes an expansion step at subcritical pressure (corresponding to solute/solvent separation), a cooling step until a liquid phase, and a pressurization-heating system to recover extraction conditions [19]. To replace this supercritical fluid cycle, which is characterized by a high-energy requirement, it is possible to regenerate solute and solvent while maintaining supercritical conditions for the solvent. In those cases, an additional mass-separating agent inducing small changes in conditions of state is added. On the one hand, a substance can be added to reduce the solvent power: For example, addition of nitrogen decreases remarkably the solubility of caffeine in carbon dioxide. On the other hand, solute can be removed from the solvent thanks to an absorbent or adsorbent for which the solute has more affinity than for the supercritical fluid. These possibilities can be preferred to the supercritical fluid cycle only if the following separations (i.e., reducing solvent power additive from supercritical fluid in the first case, or solute from the absorbent/adsorbent in the second case) are feasible with less effort than for the compression [17].

To make supercritical extraction processes more economic, separation of solute and solvent can be performed thanks to a membrane system. Sartorelli and Brunner [19] demonstrated that a membrane separation process can be proposed instead of the typical supercritical fluid cycle in the case of supercritical extraction to drastically reduce the energy losses. In fact, a stream of low volatile compounds (LVC) extracted by SC CO<sub>2</sub> can be discharged of 80%–90% of LVC using a nanofiltration membrane with a drop of pressure equal to 2 MPa instead of about 20 MPa in the typical supercritical fluid cycle.

### 7.2.1 CAFFEINE/SC CO<sub>2</sub> SEPARATION

Because caffeine extraction is an important industrial application of SC CO<sub>2</sub> technology, different studies have been recently conducted on solvent recovery by membrane separation. As the molecular weight (MW) (194 g mol<sup>-1</sup>) of caffeine is higher than CO<sub>2</sub> (44 g mol<sup>-1</sup>), classical suitable membrane for this application needs to reject caffeine while letting CO<sub>2</sub> cross through the membrane. Thus, pure CO<sub>2</sub> can be obtained on permeate side and recycled.

All published experiments on caffeine/SC CO<sub>2</sub> membrane separation are made according to the same principle. A schematic diagram presenting roughly the process is given in Figure 7.1. Carbon dioxide (1) is first liquefied in the cooler (2), pressurized in the pump (3), and heated until its working temperature in the heat exchanger (4). SC CO<sub>2</sub> is then passed through the extractor (5) to recover caffeine. This binary solution flows into the membrane module (6) where separation takes place. The operating pressure and transmembrane pressure are controlled with backpressure regulators (7) on the permeation and retention sides of the membrane. The pressure of SC CO<sub>2</sub> solution is released down to atmospheric pressure at the outlet of backpressure regulators, and the solute may be easily separated from CO<sub>2</sub> in gas/liquid separators (8).

**FIGURE 7.1** Schematic diagram of the caffeine/CO<sub>2</sub> membrane separation process.

Two main criteria are used to describe performance of separation process. The solute (caffeine) rejection rate,  $R$ , which characterizes the selectivity of the membrane, can be calculated by the following equation:

$$R = 1 - \left( \frac{C_p}{C_f} \right)$$

where  $C_p$  and  $C_f$  are solute concentrations on permeate and feed sides, respectively.

As to membrane flow properties, they can be estimated through permeability constant value  $P_c$ :

$$P_c = \frac{J}{\Delta P}$$

where  $J$  is the permeate flux of SC CO<sub>2</sub> and  $\Delta P$  the transmembrane pressure.

Values of  $R$  and  $P_c$  already published for caffeine/SC CO<sub>2</sub> membrane separation are reported in Table 7.1 and will be discussed further.

Two mechanisms can act on transport phenomena, either alone or simultaneously: adsorption and molecular sieving.

### 7.2.1.1 Separation through Adsorption Mechanism

Various authors accounted for this mechanism. Adsorption properties of caffeine, compared to *n*-octanoic acid (which presents a molecular size nearly equal to that of caffeine), on a thin porous silica membrane prepared by a sol-gel method were investigated by Fujii et al. [5]. As shown in Table 7.1, the rejection value of caffeine was positive and equal to 0.65 whereas for *n*-octanoic acid it was negative (about  $-2$ : this means that concentration in the permeate was higher than in the retentate). This quite surprising result was explained while proposing the idea of differentiated adsorption/desorption properties of solutes on the membrane surface. Both solutes are strongly adsorbed (even if adsorption rate is slightly higher for *n*-octanoic acid); but contrarily to *n*-octanoic acid, caffeine is slowly desorbed. In such a case, a permanent adsorption layer is formed, making the

**TABLE 7.1**

**Comparison of the Use of Different Types of Membranes for Caffeine/Supercritical Carbon Dioxide Membrane Separation**

Type of Membrane	Pore Diameter (nm)	Pressure (MPa)	Temperature (°C)	Rejection, $R$	Permeability Constant, $P_c$ (mol m <sup>-2</sup> s <sup>-1</sup> Pa <sup>-1</sup> )	References
Thin silica porous membrane	3.3	20	40	0.65	$2.3 \times 10^{-8}$	[5]
Hydrophilic thin silica membrane	2.5	14	35	0.98	$4.4 \times 10^{-7}$	[4]
Zeolite membrane	1.1 <sup>a</sup>	20	40	0.98	$1.1 \times 10^{-8}$	[10]
Thin layer ZrO <sub>2</sub> -TiO <sub>2</sub> nanofilter	3	8	35	1.00	$1.2 \times 10^{-7}$	[12]

<sup>a</sup> Membrane pore diameter estimated from the Dubinin–Astakhov analysis [20].

pore narrower and causing a molecular-sieving effect which is responsible for the positive observed rejection. On the contrary, *n*-octanoic acid preferentially passed within the membrane pores under the effect of partition adsorption coefficient; but it is then taken away by solvent flow and solute rejection would be negative. Fujii et al. [5] observed caffeine rejection rates equal to 0.65, which are not satisfactory for practical purpose.

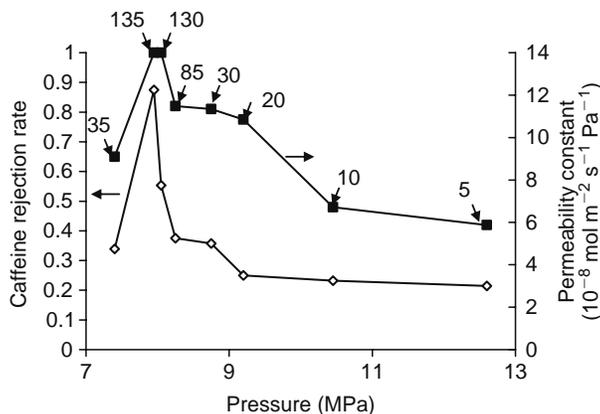

Tan et al. [4] proposed to use a thin silica membrane (prepared by them), which presents hydrophilic properties. They obtained very interesting results, i.e., a rejection rate and a permeability of  $0.98$  and  $4.4 \times 10^{-7} \text{ mol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ , respectively (see Table 7.1). To underline the effects of adsorption, the same membrane was turned hydrophobic by chemical vapor deposition (CVD) treatment and tested. A very low rejection was obtained and no significant selectivity was given by this membrane. On the basis of the fact that caffeine has more affinity with hydrophilic surfaces, these results gave evidence that adsorption was the major mechanism. Therefore, adsorption phenomenon should be taken into account for membrane choice to control solute/membrane interactions.

### 7.2.1.2 Molecular-Sieving Mechanism

Even if Tan et al. [4] could obtain very interesting results based on adsorption effects, it is worth mentioning that getting steady-state working conditions with this technology is hard to achieve: caffeine rejection rate would drop when adsorption equilibrium is approached. This constitutes a strong limitation for industrial applications.

That is the reason why lower pore size membranes working by molecular-sieving mechanism have been tested with a view to perform continuous operations. The use of a zeolite membrane (pore diameter estimated from the Dubinin–Astakhov analysis [20]: 1.1 nm) provided an interesting rejection of 0.98 [10] (see Table 7.1). In that case, caffeine adsorption was weak and zeolite membrane could not be easily fouled with the solute. Transport was mainly controlled by molecular sieving, as indicated by the good rejection rate also obtained with other molecules (e.g., lauric acid) having molecular weight close to caffeine.

Due to low membrane pore size, permeability was strongly reduced ( $1.1 \times 10^{-8} \text{ mol m}^{-1} \text{ s}^{-1} \text{ Pa}^{-1}$  as presented in Table 7.1). The challenge will consist in obtaining good separation properties with a membrane having larger pores. An idea was to try to take advantages of the formation of clusters in the near critical region [21]. Built from approximately 100  $\text{CO}_2$  molecules surrounding a solute molecule, these clusters would present a global size largely higher than the isolated solute and could lead to a high solute rejection even with larger pore membranes. In that view, Chiu and Tan [12] tested caffeine/ $\text{CO}_2$  separation under different conditions (subcritical, critical, and supercritical states) through a thin layer  $\text{ZrO}_2\text{-TiO}_2$  nanofilter (pore diameter 3 nm). Results obtained in terms of rejection rate and permeability constant are reported in Figure 7.2. It appears that there is a maximum of caffeine rejection rate (equal to 100% as reported in Table 7.1) and permeability constant around 8 MPa, which is nearly the pressure at  $\text{CO}_2$  critical point. Cluster sizes as calculated by Chiu and Tan [12] are also indicated in Figure 7.2; it is worth noting that the biggest clusters, corresponding to a total amount of 135  $\text{CO}_2$  molecules around caffeine, are formed at the same pressure. Thus, for a pressure equal to 8 MPa, the size of caffeine clusters is so high that the solute is completely rejected by the membrane through molecular-sieving effect. For  $\text{CO}_2$  molecules whose diameter is less than 0.4 nm, it becomes easier to pass through the pores inducing an optimal  $\text{CO}_2$  permeability constant. When the pressure is larger than 8 MPa, clusters are smaller and some of them can enter into membrane pores. As a consequence,  $\text{CO}_2$  permeation is hindered.

**FIGURE 7.2** Caffeine rejection rate (◇) and permeability constant (■) obtained during caffeine/ $\text{SC CO}_2$  separation on a nanofilter having a thin layer of  $\text{ZrO}_2\text{-TiO}_2$  ( $t = 308 \text{ K}$ , transmembrane pressure = 0.2 MPa). Values of estimated cluster size for each experimental point are indicated. (Adapted from Chiu, Y.-W. and Tan, C.-S., *J. Supercrit. Fluids*, 21, 81, 2001.)

This example clearly presents the importance of operating conditions such as pressure or even temperature on process performance.

However, there is a drawback with this way of doing when considering the entire extraction process. Indeed, it is worth recalling that solute extraction is generally conducted at pressure higher than the critical point; to continue after that separation of solvent by membrane at a lower pressure will need in its turn to increase again pressure before recycling pure SC CO<sub>2</sub>. These changes in pressure will be energy consuming. Nevertheless, the idea of performing separation at near critical pressure with relatively large pores still has its applicability based on the fact that high CO<sub>2</sub> permeation fluxes are obtained in addition to high solute rejection.

### 7.2.2 ESSENTIAL OILS/SC CO<sub>2</sub> SEPARATION

Essential oils are high value products mainly composed of terpene-like compounds. Their extraction with SC CO<sub>2</sub> was largely investigated and is now on the market as reported in the review of Reverchon [22].

Different studies were performed on the possibility of separating essential oils and SC CO<sub>2</sub> through a reverse osmosis membrane in a dead end flow regime. First, a cellulose acetate membrane was tested for nutmeg essential oil separation [14], which led to interesting results as retention was equal to about 0.96 and attractive CO<sub>2</sub> fluxes were obtained (permeability constant from 2.0 to  $1.1 \times 10^{-7}$  mol m<sup>-2</sup> s<sup>-1</sup> Pa<sup>-1</sup> depending on essential oil concentration in the feed). In addition, rejection rate remained stable over a period of 180 h indicating a good resistance of the membrane to the supercritical environment. These experimental results were discussed in the sense of study of transport phenomena and modeled through the irreversible thermodynamics approach [23]. Results proved a linear relationship between the CO<sub>2</sub> flux with the transmembrane pressure and the insensibility of the flux to tested temperatures (corresponding to different density values), which would indicate a predominant convective behavior during the CO<sub>2</sub> permeation through the membrane. Transmembrane pressure is thus the driving force. This was explained by the fact that CO<sub>2</sub> is able to plasticize cellulose acetate membranes. In that specific case, the swelling of the polymer chains does not induce disadvantages but facilitates the transport of the solvent.

The possibility of using commercial reverse osmosis membranes for solute/CO<sub>2</sub> separation was then extended to other essential oils such as lemongrass and orange ones [16] or to D-limonene [15].

### 7.2.3 ORGANIC COMPOUNDS/SC CO<sub>2</sub> SEPARATION

Some specific studies were performed for separation of organic compounds from SC CO<sub>2</sub> through an asymmetric polyimide membrane. Different solutes were investigated: ethanol [24], isooctane [25], and some petroleum components [26]. Results were expressed as separation factor  $\alpha_{\text{sol}/\text{CO}_2}$ :

$$\alpha_{\text{sol}/\text{CO}_2} = \frac{y_{\text{sol}}/y_{\text{CO}_2}}{x_{\text{sol}}/x_{\text{CO}_2}}$$

where  $y_i$  and  $x_i$  are the mole fractions of the component  $i$  ( $i = \text{sol}$  [for the solute] or CO<sub>2</sub>) in the permeate and in the feed, respectively.

Separation factor was from 4 to 7 for petroleum components and the best values obtained for ethanol and isooctane were 87 and 12.8, respectively.

## 7.3 COUPLING SCF EXTRACTION WITH NANOFILTRATION FOR PROCESS INTENSIFICATION

Considering that nanofiltration and supercritical fluid extraction processes are intended to act on the same chemical species (i.e., low-molecular weight compounds up to 1500 Da), Sarrade et al. proposed the idea of a hybrid process coupling the two functions, using one single pumping device and developing synergistic effects. This new process enables to conduct in one single apparatus solutes extraction and purification or fractionation of the extracted mixture. A pilot plant similar to the one presented in Figure 7.1 may be used; simply CO<sub>2</sub> obtained in the retentate stream is recycled. The role of the membrane is not here to separate solvent from solutes, but to extract selectively some kind of solutes.

The first awaited advantage of the process is to be able to work with a high permeate flux because of the low viscosity of SC CO<sub>2</sub> (10 times lower than for water). Indeed the membrane used in the process is a hybrid nanofiltration element, constituted from an inorganic substrate (TiO<sub>2</sub> with a mean pore diameter of about 10 nm) on which a nafion layer had been deposited, the prevailing mass transfer mechanism of which is convection. This fact could be checked through experiments conducted successively with water and SC CO<sub>2</sub>, flows obtained being in the opposite ratio of fluid viscosities within less than 10%.

Another expected advantage of the technique is a good control of the whole extraction/separation process. It is worth recalling that, with the classical supercritical fluid extraction process, the choice of optimal extraction conditions is often

blocked by a preoccupation with a good final fractionating of extracts. Thermodynamic conditions that make it possible to obtain a maximum extraction of compounds on one side, and an optimal selectivity during further separation of extracted species on the other side, are seldom identical; this makes it necessary to choose intermediate working conditions or expensive equipment involving several pressure release steps. Because with the new process the two functions are clearly independent; they may be optimized separately.

Finally, a reduced energy consumption may be expected because only permeate flux, and not the entire fluid stream as in classical supercritical fluid extraction process, must endure rising and falling pressure cycles.

All these advantages have been checked. First, experiments were carried out with model solutions constituted from small polyethyleneglycols—mixtures of EG/PEG400 or PEG200/PEG400—dissolved in SC CO<sub>2</sub> at temperatures and pressures between 300 and 450 K, and 10 and 30 MPa, respectively [11,27]. Then extraction/separation of natural products was investigated [28]: recovery and fractionation of unsaturated fatty acids from fish oil such as EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid), today used in human medicine for reduction of lipid absorption and prevention for heart disease; extraction and purification of  $\beta$ -carotene (provitamin A), an antioxidant supposed to prevent some cancers and also a well-known yellow-orange natural colorant of agro-food industries. For these applications, the new technique provides an original and effective way to get good quality extracts in safeguarding environmental conditions.

#### 7.4 MEMBRANE REACTORS WITH SUPERCRITICAL FLUIDS

SC CO<sub>2</sub> has some clear advantages over organic solvents for reaction purposes [29–32]. These advantages fall into different categories: environmental benefits, health and safety benefits, and process and chemical benefits. It is worth recalling that small changes in pressure or temperature cause large changes in density, enabling the fine tuning of the physical properties of the fluid, which facilitates optimization of reaction rate and selectivity. Moreover, the high diffusivity in SC CO<sub>2</sub> (one or two orders of magnitude higher than in common solvents) enhanced the mass transfer in the system, thus increasing reaction rate especially when mass transfer is limiting [33].

Catalytic reactions can be successfully performed in SC CO<sub>2</sub> as reviewed by Jessop et al. [29] and Hyde et al. [31]. Different reactions were studied in the field of homogeneous catalysis [29]—isomerization, hydrogenation, hydrosilylation, olefin metathesis, cyclization, and other C–C bond forming reactions, oxidation- or heterogeneous catalysis [31]—hydrogenation and dehydrogenation, hydroformylation, Friedel–Crafts acylation and alkylation, etherification, oxidation. It could be particularly attractive to use membrane reactors to conduct such reactions, thus pooling the advantages of supercritical fluid solvents and membrane reactors (principally the possibility of reusing and recycling the catalyst: see Chapter 36 of this book).

As shown in Figure 7.3, two membrane reactor configurations can be proposed: one with free catalyst and the other one with catalyst fixed on the membrane. In the first case, the membrane insures rejection of catalyst and keeps it in a restricted part of the system where reaction takes place. In the second case, the catalyst is fixed on the surface or in the pores of the membrane and reaction takes place at crossing.

In spite of the potential advantages of the use of a catalytic membrane reactor to perform chemical reactions in SC CO<sub>2</sub>, very few references are available on this topic. The concept was however demonstrated for the hydrogenation of 1-butene using a fluoros derivative of Wilkinson's catalyst [32]. The reaction was successfully performed in a free catalyst membrane reactor equipped with a silica membrane.

In addition to chemicals, biological catalysts such as enzymes can be used to catalyze reactions in SC CO<sub>2</sub>. Since the first attempt to operate reactions in supercritical fluids published by Randolph et al. [34], various type of enzymes were studied: lipase, oxidase, decarboxylase, dehydrogenase, proteinase, etc. [33,35–37]. The effect of different parameters was extensively reported by Ballesteros et al. [35]. Enzyme activity and stability in supercritical conditions as well as the benefits of using supercritical fluids for enzymatic reactions (improved reaction rates, control of selectivity, etc.) have been demonstrated [36].

Enzymatic reactions were then performed in both free and immobilized catalyst reactors. Knez and Habulin [38] studied sunflower oil hydrolysis in a continuous stirred tank reactor acting as a free catalyst reactor. Enzyme was retained in the reactor

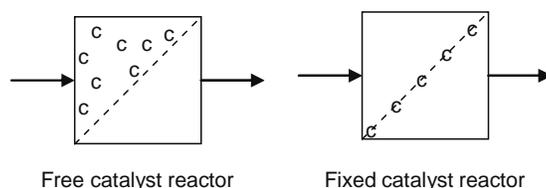

FIGURE 7.3 Schematic diagram of free and fixed catalyst reactors (c, catalyst; ---, membrane).

thanks to a polysulfon membrane placed between two sintered plates and fitted in the reactor: a conversion close to 20% was obtained in the permeate. It is also conceivable to perform biocatalyzed reactions in a fixed catalyst reactor either with permeate flow or not. Such an enzymatic membrane reactor was studied for butyl butyrate synthesis by immobilized lipase on an active membrane [39]. As permeate exit was closed, the reactor worked on a batch mode. The synthetic activity of the enzymatic membrane in SC CO<sub>2</sub> was 33-fold higher than that in most hydrophobic solvent (hexane) thus showing the suitability of this reaction media for this model reaction. In addition, by carrying on the synthesis of L-tyrosine methyl ester catalyzed by a protease in the same reactor, Lozano et al. [37] obtained a productivity 1.5-fold higher than with a fixed bed reactor constituted of celite on which enzymes were previously adsorbed. Thus the interests of the membrane reactor and of the supercritical media were proved. Finally, by working in a flow through mode (i.e., with a permeate stream) a 3-fold increase was observed in productivity which enhances the attraction of the process.

## 7.5 SUPERCRITICAL FLUID MEMBRANE CONTACTORS

Recently, a new kind of membrane processes has emerged—the so-called membrane contactors [40] in which the membrane mainly acts as a physical barrier between two phases without significant direct effect on selectivity. In such devices, the membrane acts as packing material in traditional columns but with considerably enhanced performance: it insures a well-controlled contact between the two fluids, and improved solute extraction from one side to the other. A schematic diagram of a membrane contactor (with only one membrane in this example) performing gas/liquid or liquid/liquid mass transfer is given in Figure 7.4. One fluid is flowing on one side of the membrane while the other phase circulates in counter current on the other side of the wall. Most of the time, hydrophobic porous membranes are involved, and by tight control of transmembrane pressure, the interfacial area may be maintained inside the pores [41].

Membrane contactor represents an attractive alternative process over conventional dispersed phase contactors as regards its numerous advantages: absence of emulsions, absence of flooding at high flow rates, absence of unloading at low flow rates, etc. In addition, as this process do not require density difference between fluids, it is possible to carry on extraction with an enhanced number of couples of fluids. Moreover, membrane contactors offer a very high interfacial area: 30 times higher than what is achievable in gas absorbers, and 500 times higher than what is obtainable in liquid/liquid extraction columns, leading to remarkably low height of a transfer unit (HTU) values [41].

Carrying on membrane contactors with supercritical fluids as extracting solvent can lead to very attractive extraction results due to the specific properties of supercritical fluids. Advantages of membrane contactors and supercritical fluid extraction were thus coupled in an integrated process which was patented by Robinson and Sims [42] and commercialized as the PoroCrit process. The principle is the same as presented in Figure 7.4 where one of the fluids is constituted of a subcritical or supercritical fluid. The process is conducted with high pressures on both sides of the membrane, and the solute is extracted across the membrane as driven by a concentration gradient. Any pumpable fluids including suspensions can be treated, thus inducing a wide range of applications [43]. CO<sub>2</sub>-soluble components can be stripped from aqueous stream such as fruit juices, fermentation broth, enzyme reaction mixture, wastewater, or oils. As examples, polypropylene membranes with a pore size equal to 0.2 μm and configured as hollow fiber bundles were used for orange aroma, caffeine, or vanillin extraction by SC CO<sub>2</sub> [43] and organic solvent recovery from water solutions. [44]. Although CO<sub>2</sub> is often the solvent of choice in dense gas extraction, other solvents such as compressed ethane and propane were tested for ethanol and acetone extraction from aqueous mixtures, and compared to SC CO<sub>2</sub> [45]. No significant extraction of ethanol by ethane was observed in the tested conditions while propane allows extraction but at a significantly lower level than SC CO<sub>2</sub>. Thus, SC CO<sub>2</sub> remains the more attractive solvent for this application; in addition it is worth recalling that SC CO<sub>2</sub> presents the great advantage to be nonflammable contrarily to propane.

Mass transfer in such membrane contactors was modeled for different applications involving SC CO<sub>2</sub> or other compressed gas [40,46–48].

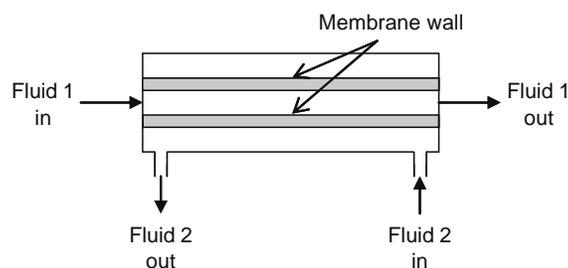

FIGURE 7.4 Schematic diagram of a membrane contactor.

## 7.6 SC CO<sub>2</sub>-ASSISTED ULTRAFILTRATION

Ultrafiltration of highly viscous liquids (particularly oils) is an uneasy and expensive operation mainly characterized by low permeate flux and high energy consumption. To overcome these difficulties, it has been already proposed to decrease viscosity by either increasing the process temperature (up to 350°C) [49] or adding specific chemicals (such as surfactants or organic solvents) [50]. However, increasing the process temperature requires very high temperatures that degrade the temperature-sensitive compounds in the oil and induce additional costs and risks, whereas adding specific chemicals raises the problem of solvent removing after filtration. That is the reason why a new cross-flow ultrafiltration process, taking advantage of the low viscosity, low surface tension, and tuneable solvent power properties of supercritical CO<sub>2</sub> to improve hydrodynamics, has been recently proposed [51,52]. Moreover, the process appears as particularly interesting for safeguarding of product quality and environment. In that alternative process, viscosity reduction is induced by fluidification of the viscous fluids following SC CO<sub>2</sub> injection.

The principle of experimental setup is presented in Figure 7.5. In addition to a loading stage, it mainly consists of a gas-pressurized cross-flow filtration circulation loop where the membrane allows the separation of the feed in two streams: the permeate and the retentate. Each stream is further separated into gas and liquid parts in the separation stage. Membranes are inorganic to ensure hard-operating conditions without failure.

With model solutions constituted of different base oils, it was first proved that, thanks to the viscosity reduction, the permeate flux is enhanced in the presence of SC CO<sub>2</sub> [52].

Then, the process was applied to an used motor oil [51]. It appears clearly that an increase of CO<sub>2</sub> pressure still permits to increase the permeate flux; but the effect is not significant above 15 MPa, which represents the optimum pressure for oil filtration. As a whole, a flux increase higher than 300% may be reached. Finally, from analysis of permeate and retentate, it follows that there is an excellent rejection rate of metals—Fe, Zn, Cu, etc.—which increases with transmembrane pressure up to more than 99% depending on species. For mass concentration factors of about 27, residues with a total metal content less than 4% of the initial load were found: oil regeneration was very effective.

In a more recent work, Rodriguez et al. [53] tried to perform the filtration of mineral oil fluidified by subcritical SC CO<sub>2</sub>. A strong fouling was observed. It was assumed that demixion occurs in the pores because of pressure reduction and shear stress, thus leading to the creation of very small bubbles of CO<sub>2</sub> which would obstruct membrane pores. Therefore, it is better to work at higher pressure to prevent this detrimental effect.

Combining this idea with the concept of membrane reactor leads to a new way for performing reaction on viscous solutions. In this view, a new process combining enzyme (as catalyst), membrane, and SC CO<sub>2</sub> has been proposed recently [54]. By replacing the classical barrier by a catalytic membrane with immobilized enzymes, the filtration system presented in Figure 7.5 may act as a catalytic membrane reactor. This new concept has been justified using as model system the interesterification of castor oil and methyl oleate catalyzed by a lipase from *Candida antarctica*. A conversion of about 30% was obtained and stability was verified on a 25 h experiment. In that case, SC CO<sub>2</sub> acts as a fluidifying agent that would enable on the one hand an interesting flux across the membrane due to viscosity reduction, and on the other hand an increase in conversion rate thanks to improved mass transfer properties.

## 7.7 MEMBRANE PREPARATION

Supercritical fluids offer new possibilities for the preparation of membranes, either inorganic or organic. Particularly, SC CO<sub>2</sub> can be usefully used instead of main classical organic solvents. Although SC CO<sub>2</sub> is a nonpolar solvent, which limits solubility of polar reactants, its combination of liquid-like density and gas-like viscosity/diffusivity leads to high reaction rate and easy recovery of products. Commonly used in organic chemistry, CO<sub>2</sub> is now proposed to be used in inorganic synthesis.

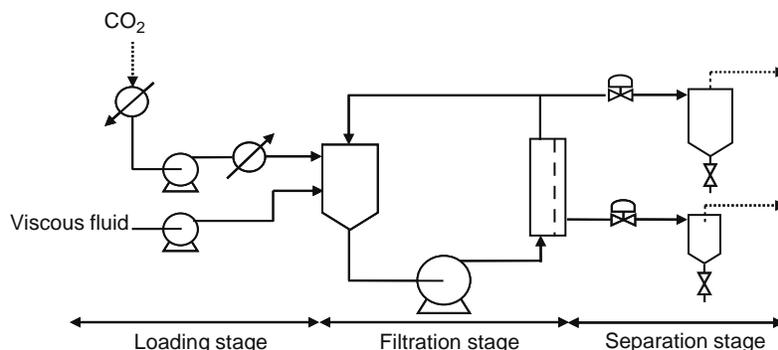

FIGURE 7.5 Experimental setup of the supercritical fluid-assisted ultrafiltration.

### 7.7.1 INORGANIC MATERIALS

A number of very interesting applications namely chromatographic stationary phase, adsorbent, catalytic support, or mineral membrane can be achieved using ultrafine metal-oxide particles. Supercritical fluids have been investigated as suitable and novel reaction media for the synthesis of such particles starting from titanium alkoxide precursors [55].

In 1999, Brasseur-Tilmant [56] presented a work dealing with modification of macroporous alumina media by  $\text{TiO}_2$  particles deposition using supercritical isopropanol. The aim was to prepare inorganic membranes for cross-flow filtration. Anatase particles were deposited on plane alumina support after thermal decomposition of titanium alkoxide precursors. A slight infiltrated zone was observed and a pore size reduction was achieved from 110 to 5 nm, leading to obtain fine ultrafiltration membranes. The main problem was to control the reaction at the membrane interface and not in the porosity, and moreover, this process was suitable for tubular membrane preparation.

Papet et al. [57] described the preparation of titanium hydroxide particles in a high-pressure stirred vessel using SC  $\text{CO}_2$  followed by particle recovery. Because of the high reactivity of the titanium alkoxide for hydrolysis, highly volatile amorphous fine powders of titanium hydroxide were formed at the pressure vessel surfaces. Scanning electron microscopy (SEM) observations of this powder (Figure 7.6) revealed a relatively homogeneous size distribution of microsized spherical particles depending on the reaction parameters.

Later, Papet [58] presented an alternative process for preparing tubular ceramic cross-flow filtration membranes. Papet's method consists of the casting of tubular mineral microfiltration membranes with titanium dioxide suspensions. The deposited particles on the porous support were then compressed and finally, the layer was consolidated by firing.

One issue to control the final pore size of the consolidated layer is to control the size of the deposited particles. Actually, using the submicronic titanium dioxide particles previously described, the preparation process allowed the authors to control the particle size (i.e., the layer pore diameter) by tuning the operating parameters during the process (temperature, pressure, contact time). The influence of the synthesis parameters on morphology and texture of titanium dioxide particles and the preliminary results concerning membrane preparation using the layer compression process show that the obtained membranes were still in the ultrafiltration range, due to shrinkage during sintering related to the low primary particles size and high specific surface area.

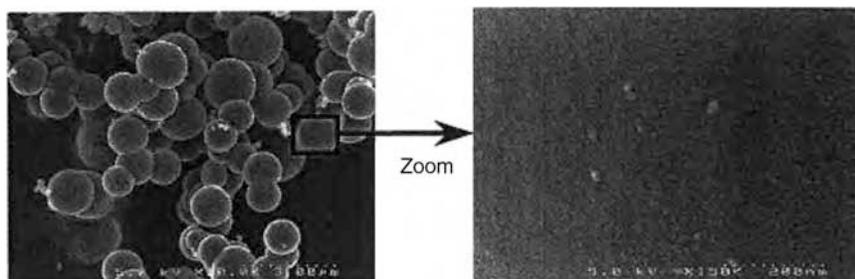

Further work in progress concerns other precursors for the production of ceramic oxide materials ( $\text{Ce}_{1-x}\text{Gd}_x\text{O}_{2-x/2}$  or doped  $\text{ZrO}_2$  and  $\text{LaGaO}_3$ ), which are oxides of interest as oxygen ion conductors [55].

### 7.7.2 POLYMERIC MATERIALS

Today the majority of polymeric porous flat membranes used in microfiltration, ultrafiltration, and dialysis are prepared from a homogenous polymer solution by the wet-phase inversion method [59–66]. This method involves casting of a polymer solution onto an inert support followed by immersion of the support with the cast film into a bath filled with a non-solvent for the polymer. The contact between the solvent and the non-solvent causes the solution to be phase separated. This process involves the use of organic solvents that must be expensively removed from the membrane with posttreatments, since residual solvents can cause potential problems for use in biomedical applications (i.e., dialysis). Moreover, long formation times and a limited versatility (reduced possibility to modulate cell size and membrane structure) characterize this process.

The difficulty in analyzing the phase inversion process is due to the interactions between the three components involved, and to the complex diffusion and convective processes that play an important role during the membrane formation. However, many researchers agree that there are two dominating factors controlling the formation of phase inversion membranes: thermodynamics and kinetics, correlated to each other during the solidification of casting solutions.

A new technique in which SC  $\text{CO}_2$  is used to induce the phase separation of the polymer solution has been recently proposed by different authors. Kho et al. [67] used compressed  $\text{CO}_2$  for the formation of Nylon 6 membranes. The process was

**FIGURE 7.6** Spherical nanophased titanium hydroxide particles obtained in SC  $\text{CO}_2$  from hydrolysis and condensation of tetraisopropyl-orthotitanate at 323 K and 30 MPa.

performed at 35°C with the final pressure up to 174 bar for 30 min. Thin films (thickness ranging from 150 to 250  $\mu\text{m}$ ) were obtained with uniform structures and cellular pores of 0.4  $\mu\text{m}$  in diameter. Matsuyama et al. on their side studied the formation of thin polystyrene membranes [68] and analyzed the effect of several process conditions (temperature, pressure, polymer concentration) on the pore size. They also investigated [69] the influence of different solvents during the formation of cellulose acetate membranes. Finally, Reverchon and Cardea [70] looked at the formation of cellulose acetate membranes from acetone using the supercritical  $\text{CO}_2$ -assisted phase inversion method. They reported the effect of an increase/decrease in affinity between supercritical  $\text{CO}_2$  and acetone (i.e., increasing/decreasing the supercritical  $\text{CO}_2$  solvent power). They also observed that polymer concentration influences the mean diameter of the cells that ranges from 2 to 50  $\mu\text{m}$  by varying the polymer concentration from 40% to 5% (w/w). A membrane formation mechanism was postulated. Yet more recently, these authors have investigated [71] the possibility of obtaining polysulfone membranes with a flexible and solvent-reduced supercritical  $\text{CO}_2$ -assisted technique. Polysulfone is a “green material,” biodegradable and biocompatible, which could be particularly interesting for medical applications.

Compared with the liquid-phase inversion method, this phase separation process has several advantages [59]:

- SC  $\text{CO}_2$  can dry the polymer membrane rapidly and totally without the collapse of the structure due to the absence of a liquid–vapor interface. The membrane can be obtained without additional posttreatments because there are no solvent residues.
- It is easy to recover the liquid solvent; it is dissolved in SC  $\text{CO}_2$  and can be removed from gaseous  $\text{CO}_2$  in a separator located downstream the membrane formation vessel.
- SC  $\text{CO}_2$  versatility allows modulation of the membrane morphology, cells, and pore size by simply changing the operative conditions.
- $\text{CO}_2$  is nontoxic, nonflammable, and cheap.

## 7.8 CONCLUSIONS

The review here proposed shows clearly that the use of a membrane in the presence of a supercritical fluid makes it possible the design of very attractive and powerful processes to improve transfer or reaction, to set in contact different phases, to fluidify highly viscous liquids, etc. or for the preparation of new generations of membranes. This is to be connected to the specific thermodynamic and transport properties of supercritical fluids and the particular environment that is created for all these operations.

For industrial applications, specific constraints flow from particular conditions of pressure and temperature. But there is no real impediment, which could obstruct practical implementation of these processes. Overall, the major interest of all these processes is that they are safeguarding for environment and product quality (which is essential in particular when working with biological compounds).

The performance of a membrane process is a function of the intrinsic properties of the membrane, the imposed operating and hydrodynamic conditions, and the nature of the feed. This chapter describes methods available to enhance performance by various techniques, mainly hydrodynamic but also chemical and physical. The focus is on the liquid-based membrane processes where performance is characterized by attainable flux, fouling control, and separation capabilities. The techniques discussed include secondary flows, flow channel spacers, pulsed flow, two-phase flow, high shear devices, electromagnetic effects, and ultrasound.

## 8.1 PROCESS LIMITATIONS AND ENHANCEMENT

Performance is usually compromised by concentration polarization and fouling, which is explained below. This is followed by a discussion of the strategies available to limit their impact.

### 8.1.1 LIMITATIONS DUE TO CONCENTRATION POLARIZATION AND FOULING

A range of membrane processes are used to separate fine particles and colloids, macromolecules such as proteins, low-molecular weight organics, and dissolved salts. These processes include the pressure-driven liquid-phase processes, microfiltration (MF), ultrafiltration (UF), nanofiltration (NF) and reverse osmosis (RO), and the thermal processes, pervaporation (PV) and membrane distillation (MD), all of which operate with solvent (usually water) transmission. Processes which are solute transport are electrodialysis (ED) and dialysis (D), as well as applications of PV where the trace species is transmitted. In all these applications, the conditions in the liquid boundary layer have a strong influence on membrane performance. For example, for the pressure-driven processes, the separation of solutes takes place at the membrane surface where the solvent passes through the membrane and the retained solutes cause the local concentration to increase. The concentration profile of the retained solutes depends on the balance between the convective drag toward and through the membrane (resulting from the permeation flux) and back transport away from the membrane. The properties of this deposited layer could be either reversible or irreversible.

Concentration polarization is the reversible buildup of dissolved or suspended species in the solution phase, as depicted in Figure 8.1. The influence of concentration polarization on performance varies with different membrane processes. For RO and NF, concentration polarization can result in a significant increase in osmotic pressure. As a result, higher delivery pressure is required to provide the driving force to achieve reasonable flux values. For UF, the macromolecular solutes and colloidal species could have modest osmotic pressures and also the concentration at the membrane surface can rise to the point of incipient gel formation which is typically in the range of 20%–60% solute by volume [1]. This can lead to a transition from concentration polarization to membrane fouling. For MF membranes without a fouling layer formed on the surface or in the pores, concentration polarization of macromolecules should be negligible because large pore membranes are essentially not retentive to most macromolecules. However, MF membranes can experience particle polarization due to the retention of colloids and particulates.

Concentration polarization and particle polarization are related to the permeation-induced buildup of the concentration profile on the membrane surface without changing the characteristics of the permeability and selectivity of the membranes. Membrane fouling is related to irreversible changes in membrane permeability due to retained species deposition on the surface or the internals of the membrane. Figure 8.2 shows typical forms of membrane fouling applicable to MF and UF, including pore constriction, pore blocking, and gel/cake formation. This can also apply to NF and RO. Consider a particle with diameter  $d_p$  and a pore with  $d_{\text{pore}}$ , when  $d_p \ll d_{\text{pore}}$ , the particle can enter the membrane pore and pore constriction may occur. When  $d_p = d_{\text{pore}}$ , deposition of the particle onto the membrane surface may cause pore blocking. For  $d_p > d_{\text{pore}}$ , particles will be

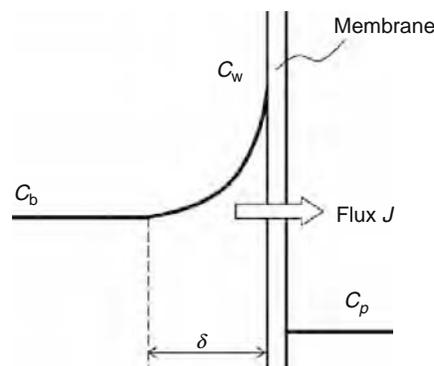

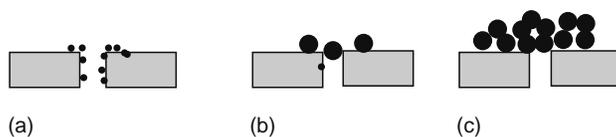

FIGURE 8.1 Schematics of the concentration polarization boundary layer for membrane filtration.

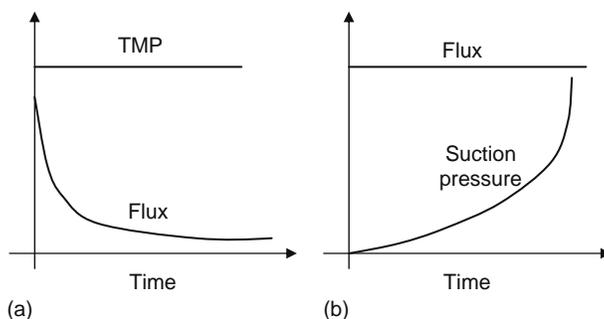

**FIGURE 8.2** Fouling schematics for different mechanisms. (a) Pore construction, (b) pore blocking, and (c) cake formation.

retained in a cake on the membrane surface. In a membrane filtration process, fouling could be a combination of different mechanisms due to the distribution of species sizes in real feeds. Usually, in the initial stages, membrane fouling could be dominated by pore constriction and pore blocking. Once the first cake layer has formed on the membrane surface, gel/cake formation may become the dominant fouling mechanism. The filtration behavior of the cake layer, including compressibility and permeability, is a function of the properties of the colloids deposited. For highly compressible cakes, usually formed by particles with strong interparticle interactions, the cake resistance may be dominated by a very thin layer adjacent to the membrane surface. Analogous phenomena occur with macro solutes and sparingly soluble solutes because concentration polarization frequently leads to fouling.

Membrane fouling may result in a significant increase in filtration resistance, leading to unstable filtration behavior. The pressure-driven membrane processes can be operated either with constant feed pressure or in the constant flux mode. For constant pressure operation where the transmembrane pressure (TMP) is maintained at a constant value during the filtration, the flux will decline with time due to the increased filtration resistance as shown in Figure 8.3a. It is observed that a quasi-steady state can be reached for crossflow membrane filtration when the flux drops to a value called the limiting flux where the particle deposition caused by the flux is balanced by the crossflow-induced particle back transport. The limiting flux is independent of the TMP and the filtration resistance but depends on the hydrodynamically induced back transport and is a function of surface shear, particle size, and the physical characteristics of the solution. The limiting flux can be experimentally determined or estimated based on the mechanisms of back transport, as discussed below. Membrane filtration can also be operated in the constant flux mode by extracting permeate at a constant flow rate, for example by using a suction pump. With fixed flux, the suction pressure and TMP could theoretically be maintained steady if the flux is below a critical flux (see Section 8.1.2). More typically, suction pressure will increase with time due to membrane fouling as depicted in Figure 8.3b. Constant flux operation has the advantage of avoiding rapid development of membrane fouling caused by a high initial flux as typically found with constant pressure filtration. This observation leads to the critical or sustainable flux strategy to enhance the performance of membrane processes.

### 8.1.2 CRITICAL FLUX AND SUSTAINABLE FLUX

For crossflow filtration, the tangential flow tends to sweep the particles away from the membrane surface or promote particle back transport. It can be assumed that the particle will not deposit onto the membrane surface if the permeate flux is controlled below a value such that the drag force exerted on the particle by the permeate flow is smaller than the lift force caused by the crossflow. Based on experimental observation, Field et al. [2] first suggested that there may be a critical flux below which species in the feed have negligible interactions with the membrane and the TMP is similar to that of pure water at the same flux (the strong form of critical flux). If some interaction (such as adsorption) occurs, the flux at which the TMP-flux line becomes nonlinear is the weak form of the critical flux. Using a technique called direct observation through the membrane (DOTM), Li et al. [3] were able to visually confirm that a clean membrane without deposition was attainable during the microfiltration of latex particles if the flux was controlled below a certain critical value that is dependent on the crossflow velocity and particle size.

**FIGURE 8.3** TMP and flux profiles for (a) constant pressure and (b) constant flux filtration.

A number of mechanisms have been related to the particle back transport induced by crossflow. Among them, Brownian diffusion, shear-induced diffusion, and initial lift mechanisms are most widely accepted [4]. The Brownian diffusion model suggests that molecular diffusion in the boundary layer is responsible for the particle back transport, implying that the concentration polarization is inevitable in membrane filtration. Shear-induced diffusion arises from multiparticle interactions induced by shear flow. The essential requirement for these mechanisms is that the particle concentration should be sufficiently high to result in a significant particle interaction [5]. Inertial lift was first studied by Segre and Silberberg [6], who identified a “tubular pinch effect” in which lateral migration occurs both from the center and from the tube wall toward an eccentric equilibrium position for a range of particle size and flow conditions. Inertial lift was regarded to arise from nonlinear interactions of a particle with the surrounding flow field under conditions where the Reynolds number ( $Re$ ) based on the particle size is not negligible and so the nonlinear inertial terms in the Navier–Stokes equations play a role. The critical flux for different back transport mechanisms can be expressed in the following general form:

$$J_{cr} = c\gamma^n r_p^m \phi_b^p L_f^q \eta^s \quad (8.1)$$

where

- $\gamma$  is the shear rate at the membrane surface
- $r_p$  is particle radius
- $\phi_b$  is the solid volume fraction in the feed
- $L_f$  is the filter length
- $\eta$  is the viscosity
- $c, n, m, q,$  and  $s$  are coefficients

Equation 8.1 highlights the importance of shear rate in raising critical flux, and illustrates why the majority of performance enhancing techniques involve methods of increasing surface shear phenomena. Table 8.1 shows the coefficients in Equation 8.1 for different back transport mechanisms.

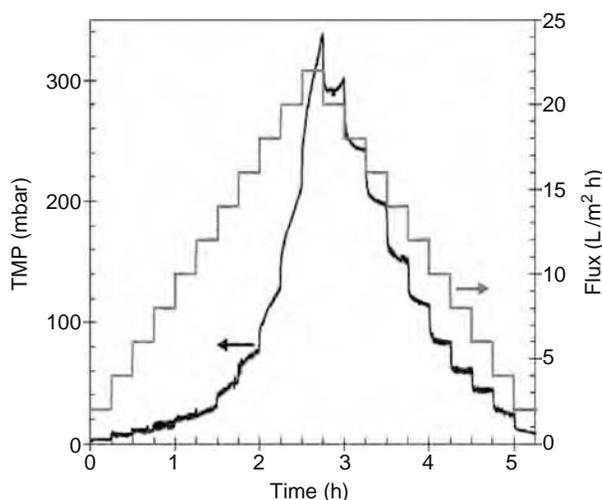

For a given crossflow filtration, the dominant particle back transport mechanism may depend on the shear rate and the particles size [4]. Brownian diffusion is only important for particles smaller than only a few tenths of a micron in diameter with relative low shear, whereas inertial lift is important for particles larger than several tens of microns with higher shear rates. Shear-induced back transport appears to be important for intermediate particle sizes and shear rates. Li et al. [7] reported that the shear-induced mechanism was able to predict fluxes comparable with the critical fluxes identified by the DOTM.

For mixed feed, the limiting critical flux will be that of the component with lowest critical flux; in practice, this may be impractically low and a sustainable flux, requiring infrequent cleaning, may be adopted. For soluble species and fine colloids, the critical flux can be considered as the flux below which the wall concentration does not initiate fouling.

One of the earliest approaches to sustainable operation was the Bactocatch process applied in the dairy industry [8] where in effect the TMP was maintained at a low-controlled value to limit flux and fouling. In this process, the axial feed flow in a ceramic tubular module was matched by the recirculation of permeate in the shell. It is now recognized that constant flux operation applying critical or sustainable flux concepts is attractive. A prime example is the large-scale membrane bioreactor (MBR) used for wastewater treatment where the long-term stable operation with minimum membrane chemical cleaning is desirable. In this application, controlling flux below the sustainable flux has become a common strategy to fight membrane fouling. The critical flux can be experimentally identified through constant flux filtration experiments by incrementing the flux until the TMP (or suction pressure) is no longer steady as depicted in Figure 8.4. For a real feed, the suction pressure may slightly increase even at very low flux. Figure 8.4 shows a typical TMP profile with stepped flux increase at 2 L/m<sup>2</sup> h obtained in filtration of synthetic wastewater [9]. From Figure 8.4, it can be seen that the increase in the rate of TMP became significant when the flux was higher than 10 L/m<sup>2</sup> h. However, closer observation indicates that the TMP started to increase even at a flux

**TABLE 8.1**  
**Coefficient in Equation 8.1 for Different Mechanisms**

Coefficients	Brownian Diffusion	Shear-Induced Diffusion	Inertial Lift
$c$	1.31	0.072	0.036
$m (r_p)$	-0.67	1.33	3
$n (\gamma)$	0.33	1	2
$p (\phi_b)$	-0.33	-0.33	0
$q (L_f)$	-0.33	-0.33	0
$s (\eta)$	-1	-0.33	0

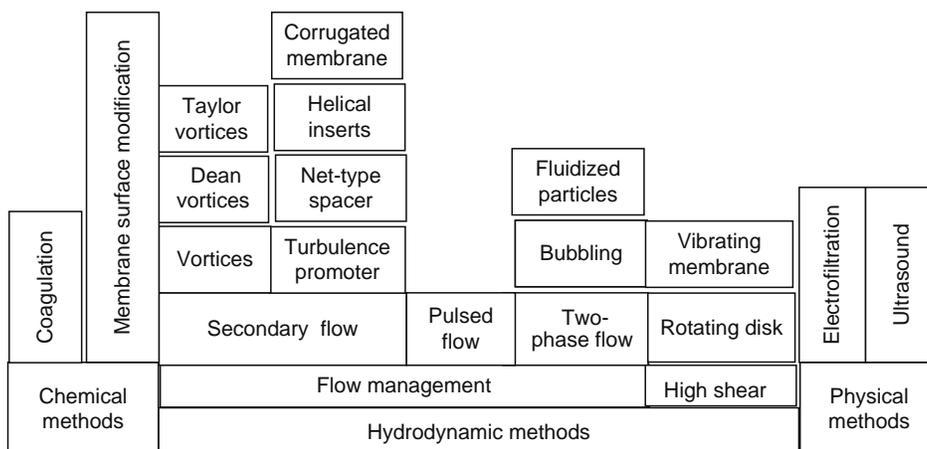

**FIGURE 8.4** Determination of the critical flux by stepped TMP increase protocols. (From Figure 3 in Le-Clech, P., Jefferson, B., Chang, I.S., and Judd, S.J., *J. Memb. Sci.*, 227, 81, 2003. With permission.)

as low as 2 L/m<sup>2</sup> h [9]. For cases like this (i.e., an MBR), a specific rate of increase in TMP (dTMP/dt) can be used for determination of the critical flux or the sustainable flux as discussed by Le-Clech et al. [9].

**8.1.3 METHODS TO CONTROL CONCENTRATION POLARIZATION AND MEMBRANE FOULING**

Figure 8.5 summarizes the range of methods used to control concentration polarization and membrane fouling. These include chemical, hydrodynamic, and physical methods. The most direct chemical approach to control membrane fouling is modification of the surface properties of the membranes, such as surface charge and hydrophilicity. Some methods used to modify membrane properties include heterogeneous chemical modification [10], adsorption of hydrophilic polymers [11], irradiation methods [12], and low temperature plasma activation [13]. The chemical methods also include application of coagulants to change particle size distribution in the treated feeds (note the importance of particle size in Equation 8.1). Addition of inorganic salts and polyelectrolytes as well as pH shifts in the feeds can destabilize colloids and result in formation of larger flocs, reducing the concentration of the colloids in the feeds that are mainly responsible for formation of high resistance. For applications such as macrosolute UF, pH adjustment to the feed can alter solute–membrane interactions and reduce fouling [14].

Most of hydrodynamic methods have focused on increasing the particle back transport from the membrane–liquid interface by increasing the shear rate and the flow instability in the boundary layer. These techniques include secondary flows, spacers and inserts, pulsed flow, high shear rate devices, vibrations, and two-phase flow. The physical methods that are currently been tested to enhance filtration performance of membranes include the application of electric fields and ultrasound.

**FIGURE 8.5** Methods used for performance enhancement of membrane filtration.

The performance enhancement by a specific hydrodynamic technique is assessed by comparing the steady flux obtained under the same filtration conditions with and without imposition of the hydrodynamic technique. However, since most of the hydrodynamic techniques used for flux enhancement also result in an increase in the energy consumption, there is a trade-off between capital cost (related to flux enhancement) and operating cost (related to energy consumption). In filtration processes, the energy will be dissipated by crossflow and driving the permeate going through the membrane. Thus the overall power expenditure within the module ( $P_d$ ) can be approximated by

$$P_d = |Q_f \Delta P_L + Q_p P_{tm}| \quad (8.2)$$

where

$Q_f$  is the crossflow flow rate

$Q_p$  is the permeate flow rate

$P_{tm}$  is the TMP

$\Delta P_L$  is the pressure loss in the module (a part of which is used to generate surface shear)

Then the energy expenditure per unit volume of permeate in  $\text{kw h/m}^3$  is

$$E_d = \frac{1}{3.6 \times 10^6} \left( \frac{Q_f \Delta P_L}{Q_p} + P_{tm} \right) \quad (8.3)$$

The costs of the filtration processes include module and energy cost. The module cost depends on the membrane area (inversely related to flux), so the module cost per unit filtrate can be calculated by

$$\text{Module cost } (\$/\text{m}^3) = \left( \frac{1}{J_d} \right) (\text{s/m}) \times C_{\text{mem}} (\$/\text{m}^2\text{s}) \quad (8.4)$$

where

$J_d$  is the design flux of the filtration process

$C_{\text{mem}}$  is the cost of capital related to membrane area per unit time

The critical flux or sustainable flux can be used as the design flux for the processes, which is to be enhanced by the hydrodynamic techniques applied.

The energy cost can be estimated by

$$\text{Energy } (\$/\text{m}^3) = E_d (\text{kW h/m}^3) \times \text{cost } (\$/\text{kW h}) \quad (8.5)$$

Most of hydrodynamic techniques will reduce the module/membrane cost due to enhancement of the design flux but increase the energy cost due to increased pressure drop through the module. The optimal process design should result in a minimum total cost or the sum of the energy and module cost. An example of this trade-off is described in Section 8.3. The important point to note is that the performance enhancing techniques involve a cost that must provide a benefit and return on investment.

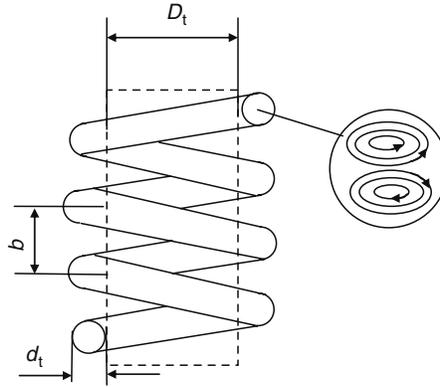

## 8.2 SECONDARY FLOWS

### 8.2.1 DEAN VORTICES

#### 8.2.1.1 Characteristics of Dean Flow

Dean vortices are the secondary flows that occur in the cross section of a curved channel or helically coiled tubes. Figure 8.6 shows the secondary flow developed in a helically coiled tube. When fluid flows through the helically curved tube, the faster elements of the fluid in the center of the tube tend to be moved outward by centrifugal force, while the slower elements of the fluid are forced inward to maintain mass balance, resulting in counter rotating vortices in the cross section of the channel as shown in Figure 8.6. The intensity of the secondary flow depends on the fluid flow in the tube and the geometric features of the curved channel, characterizing by the so-called Dean number ( $De$ ):

$$De = Re \sqrt{\frac{d_t}{D_t}} \quad (8.6)$$

**FIGURE 8.6** Dean flow formed in a coiled helical tube.

where

$D_t$  is the coil diameter

Reynolds number,  $Re = d_t V_m / \nu$

$d_t$  is the tube diameter

$V_m$  is the mean azimuthal velocity

$\nu$  is the kinematic viscosity

A modified curvature diameter  $D'_t$ , which takes into account the torsion effect and varies with the pitch  $b$ , is formulated as below for helically coiled tubes:

$$D'_t = D_t \left[ 1 + \left( \frac{\pi}{b D_t} \right)^2 \right] \quad (8.7)$$

It is suggested that the appearance of the Dean vortices depends on the magnitude of the Dean number. Although it is suggested that the secondary flow can only appear above a critical Dean number [15], flow simulation indicates that a secondary flow field could be developed even at very low Dean number [16]. However, the effect of the secondary flow on mass and heat transfer is difficult to detect experimentally at Dean numbers lower than about 20.

The following empirical correlation from Mishra and Gupta [17] can be used to calculate the friction factor ( $f_c$ ) in a torus, coil, or helical tube under the conditions: Laminar,  $1 < De < 3000$ ;  $3 \times 10^{-3} < d_t/D_t < 0.15$ ;  $0 < (b/D_t) < 25.4$ .

$$f_c = f_s [1 + 0.033(\log De)^4] \quad (8.8)$$

where  $f_s$  is the friction factor in a similar straight tube. For Newtonian laminar flow,  $f_s$  can be calculated by

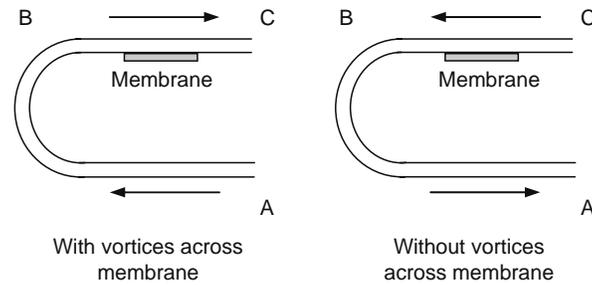

$$f_s = \frac{64}{Re} \quad (8.9)$$

The axial pressure drop due to friction for a helical coil tube can then be calculated by

$$\Delta P_L = f_c \frac{L_f}{d} \frac{1}{2} \rho V_m^2 \quad (8.10)$$

### 8.2.1.2 Dean Flow-Enhanced Membrane Process

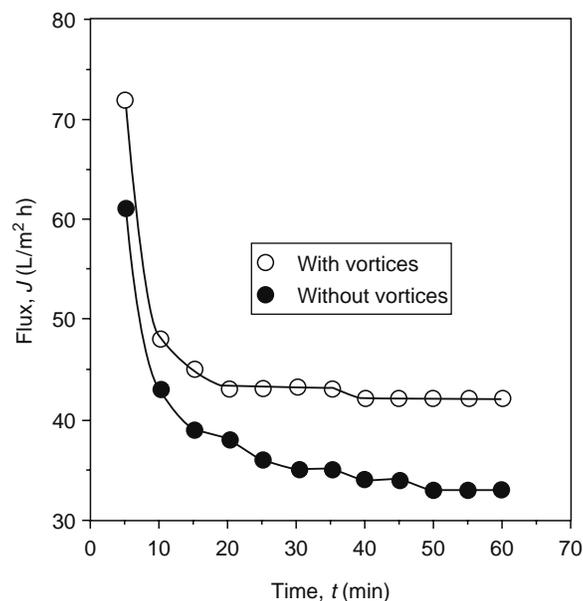

Experimental evidence has demonstrated that Dean vortices can be effective for enhancement of membrane performance under laminar conditions [18]. As flow conditions approach the transition and turbulent flow regimes, straight membranes have a better mass transfer and higher wall shear rate than in flows with curved membrane channels. The effects of Dean vortices on the performance of membrane filtration have been studied experimentally and theoretically by Belfort and coworkers [19–22]. Mallubhotla and Belfort [21] assessed the filtration of suspensions of polydispersed polystyrene particles (mean diameter 25  $\mu\text{m}$ ) and silica particles (mean diameter 20  $\mu\text{m}$ ) with and without the presence of Dean flow using an 180° U-bend channel

**FIGURE 8.7** Configuration of Dean generator test cell. (Adapted from Figure 1 of Brewster, M.E., Chung, K.Y., and Belfort, G., *J. Membr. Sci.*, 81, 127, 1993.)

with a membrane attached on the lower surface of the upper linear part of the U channel after the curve. With such a test cell, the filtration can be conducted with and without the appearance of the Dean vortices in the crossflow over the membrane by using the flow setting shown in Figure 8.7. Figure 8.8 shows the permeation flux-time profiles for filtration of the polydispersed polystyrene particles with and without the Dean vortices. It can be seen from this figure that a significantly higher pseudo-steady state can be reached at an earlier stage in the filtration with Dean vortices than that without Dean vortices, indicating an improvement in filtration performance.

Although some of the earlier work on Dean flow-enhanced membrane filtration was conducted with modules designed by placing a half spiral tube onto a flat sheet membrane [19], most recent studies have been carried out with helical hollow fiber membrane modules. Moulin et al. [23] compared the ultrafiltration of colloidal bentonite and dextran solution with a coiled and a straight hollow fiber membrane, with hollow fiber configuration of  $d_{fi} = 0.93$  and  $0.7$  mm in the laminar flow region. It was reported that the secondary flow induced by the coiled geometry could enhance the limiting flux by up to a factor of 2 or 3 for the colloidal suspension and the macromolecular solution, respectively. The flux enhancement increased when the coil diameter was reduced from 11 to 4.1 cm, implying increased enhancement with increase in Dean number (Equation 8.6). Mallubhotla et al. [22] studied the effect of Dean vortices on nanofiltration of inorganic and amino acid solutions using helical hollow fiber membrane modules that were made by wrapping a 0.27 mm fiber (inner diameter) around a steel rod of 3.18 mm diameter. The results showed the flux of the helical module was about 16% higher for 0.02 mol KCl and  $K_2SO_4$  solution and about 32% higher for  $K_3PO_4$  than those with the straight module. For filtration of different amino acid solutions, the flux enhancement by Dean flow was found to be a strong function of the pH of the solution, ranging from less than 5% to 35% in the pH range of 3–10 with an increased enhancement at high pH. Although helically coiled hollow fibers have proved to be effective for flux enhancement, no large-scale commercial hollow fiber membrane module has adopted the design to date, probably due to the difficulty of fabrication.

**FIGURE 8.8** Flux-time profile with and without Dean flow for filtration of S/DVB particles. (From Figure 3 in Mallubhotla, H. and Belfort, G., *J. Membr. Sci.*, 125, 75, 1997. With permission.)

## 8.2.2 TAYLOR FLOW

### 8.2.2.1 Characteristics of Taylor Flow

Another method that has been used to promote secondary flow is the generation of Taylor vortices in the annulus of two concentric cylinders with a rotating cylindrical filter. Figure 8.9 shows a typical rotatory membrane module that consists of two coaxial cylinders with the inner cylinder driven by an electric motor and the outer fixed. The membrane is usually attached to the inner rotating cylinder. The feed flows along the  $z$ -axis in the annular gap between the two concentric cylinders with the permeate were collected by a duct along the axis of rotation. When the inner cylinder rotates, a hydrodynamic regime is generated with annual counter rotating vortices (Taylor vortices) as shown in Figure 8.10. The Taylor flow can be characterized by the Taylor number:

$$Ta = \frac{\omega R_1 \Delta R}{\nu} \left( \frac{\Delta R}{R_1} \right)^{0.5} \quad (8.11)$$

where

$\omega$  is angular velocity

$R_1$  is radius of the rotating cylinder

$R_2$  is the inner radius of the fixed cylinder

$\Delta R = (R_2 - R_1)$ , i.e., the width of the annular gap

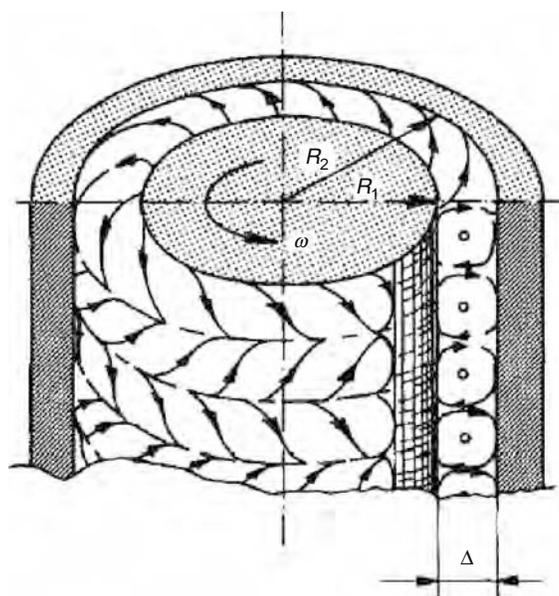

FIGURE 8.10 Schematic illustration of the Taylor vortices in the annulus of an axial rotating dynamic membrane filter. (From Figure 3 in Kroner, K.H. and Nissinen, V., *J. Membr. Sci.*, 36, 85, 1988. With permission.)

When the Taylor number exceeds a critical value ( $Ta_c$ ), a transition from stable Couette flow to vortical Taylor–Couette flow occurs. The critical Taylor number can be calculated by [24]:

$$Ta_c = 20.1 + 13.6 \left( \frac{\Delta R}{R_i} \right) + 1.4 \left( \frac{\Delta R}{R_i} \right)^2 \quad (8.12)$$

### 8.2.2.2 Membrane Filtration with Taylor Flow

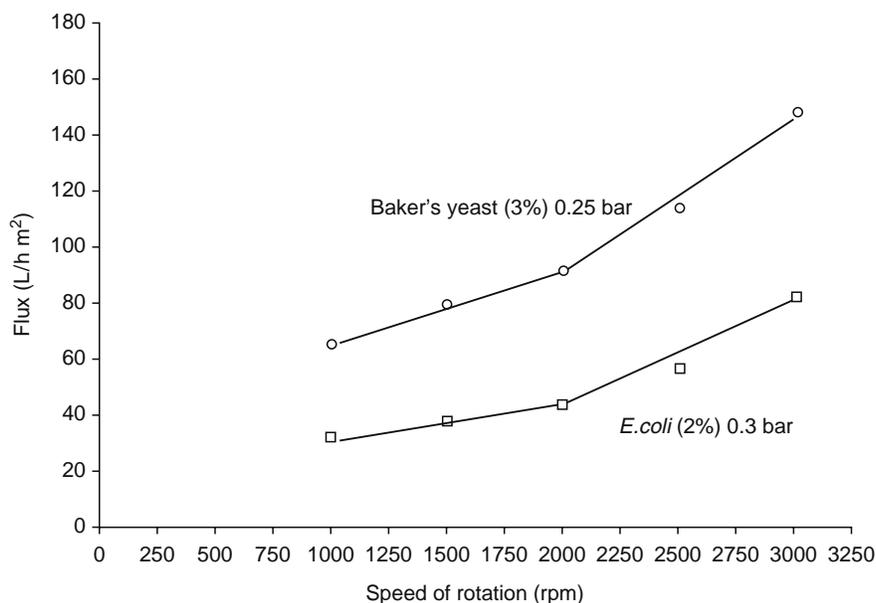

The rotating filter has been tested for a wide range of applications, including concentration of biological suspensions [25], skim milk separation [26], separating plasma from whole blood [27], and oil–water separation [28]. The flux obtained with a rotating filter will depend on the rotating speed, operating pressure, and the structure of the filter such as the gap size and the roughness of the rotating surface. It was reported that a flux from 50 to 150 L/m<sup>2</sup> h has been achieved for UF of 20% cutting oil emulsion under conditions of 300 kPa and rotating speeds from 210 to 2550 rpm [28]. Kroner and Nissinen [25] reported fluxes of 60–140 L/m<sup>2</sup> h for MF of 3% Baker’s yeast suspensions at 25 kPa and a flux range 30–75 L/m<sup>2</sup> h for MF of 2% *Escherichia coli* broth at 30 kPa in the rotating speed range 1000–3000 rpm. For cell concentration, a final batch concentration of 30%–70% for baker’s yeast and 9%–53% for bacterial suspensions, accompanied by a high protein transmission, was reported with the application of the rotating filter [25].

Figure 8.11 shows the effect of rotation speed for filtration of baker’s yeast suspension and *E. coli* fermentation broth [25]. In both cases, the increase in rotation speed in the range of 1000–3000 rpm, which corresponds to a range of  $Ta$  from about 2000–6000 for the test device, resulted in a substantial increase in flux with a transition point observed at a rotation speed of 2000 rpm—this corresponds approximately to a Taylor number of 3500, where turbulent Couette flow can be assumed.

An empirical correlation which expresses the Sherwood number ( $Sh$ ) as a function of the Taylor number was proposed by Holeschovsky and Cooney [29] as

$$Sh = 1.26Ta^{0.5} \left( \frac{2d}{R} \right)^{0.17} Sc^{0.33} \quad (8.13)$$

The main limitation of the axially rotating filter is difficulty of scale-up. Most of the reported experiments have been carried out with lab-scale units with the radius of the rotating cylinder <50 mm and the total filtration area <0.05 m<sup>2</sup>.

**FIGURE 8.11** Effect of rotating speed on permeate flux for filtration of baker’s yeast and *E. coli* suspensions. (From Figure 8 in Kroner, K.H. and Nissinen, V., *J. Membr. Sci.*, 36, 85, 1988. With permission.)

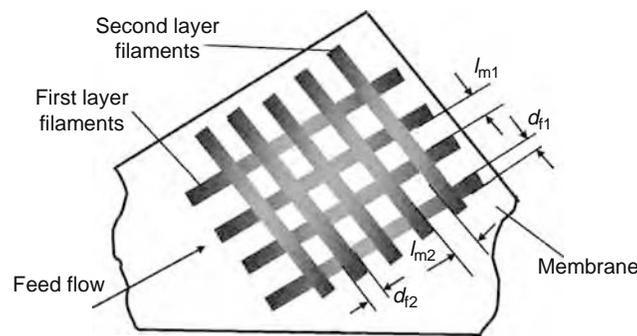

FIGURE 8.12 Schematics of net-type spacers.

## 8.3 FLOW CHANNEL SPACERS

### 8.3.1 NET-TYPE SPACERS

#### 8.3.1.1 Geometrical Characteristics of Net-Type Spacers

The net-type spacer is a key feature in the spiral wound module (SWM) widely used in RO (desalination), NF (water treatment), and some large-scale applications of UF (dairy and food). The spacers in the SWM have the dual function of keeping adjacent membranes apart to form a feed channel and of promoting turbulence in the feed channel. As shown in Figure 8.12, the net-type spacer usually consists of two layers of cylindrical filaments joined together to form a screen-like mesh. The typical mesh geometries include square, rhomboid, and parallelogram, with cell sizes of the order 4 mm and mesh heights of 1–2 mm. The diameter of the filaments in the top and the bottom layers could be identical (symmetric spacers) or different (asymmetric spacer). The main characteristic parameters of the spacers include filament diameter, mesh size, and the angle between the filaments (Figure 8.12). Other defined spacer parameters include the specific area,  $S_{vsp}$  [30], and spacer voidage  $\varepsilon$  [31].

#### 8.3.1.2 Effect of Spacer Geometry

In the SWM flow through the spacer-filled channel induces unsteady flows and increases local shear rates and local mixing, which reduce the boundary layer thickness and the concentration polarization. The mass transfer and pressure drop in a spacer-filled channel can be significantly affected by the geometric characteristics of the spacer. Figure 8.13 shows some typical commercial net-type spacers studied by Da Costa et al. [32]. Table 8.2 shows their characteristic parameters. Figure 8.14 shows the steady flux at different TMPs for filtration 1 g/L dextran (average molecular weight 500,000 Da) using a Koch Systems HFK-131 polysulphone 5 KDa UF membrane in a test cell with channel dimensions of 25 mm width and 285 mm long. Comparing the flux obtained with and without spacers, the flux was significantly higher (three to fivefold) for the filtration with

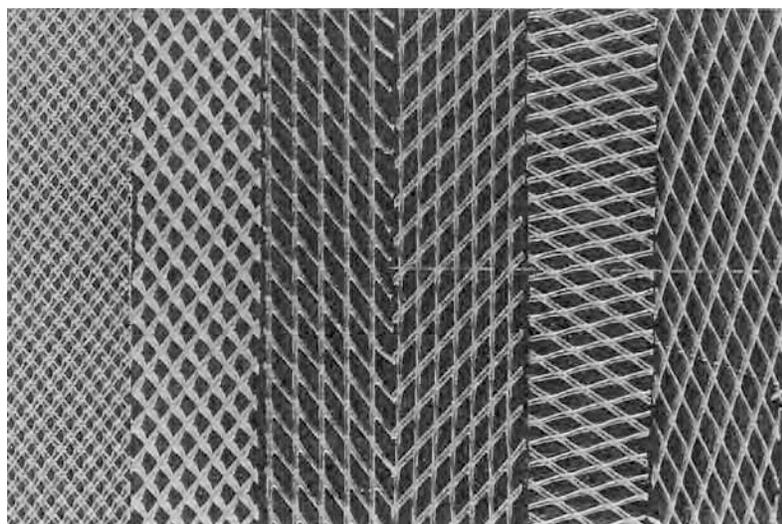

FIGURE 8.13 Typical commercial net-type spacers. (From Figure 2 in Da Costa, A.R. and Fane, A.G., *Ind. Eng. Chem. Res.*, 33, 1845, 1994. With permission.)

**TABLE 8.2**

<sup>b</sup> Angle between the filament and channel axis (main flow direction).

<sup>c</sup> Thin and thick filaments.

<sup>d</sup> Short and long filaments.

spacers. Inspection of Figure 8.14 shows that the flux enhancement was significantly influenced by the spacer geometry. The spacers also increased the channel pressure loss from about 1 kPa (empty channel) to as high as 167 kPa.

Da Costa et al. [32] showed that the mass transfer coefficient for various net-type spacers can be represented by a Sherwood correlation:

$$Sh = cRe^m Sc^p \left( \frac{d_h}{L_s} \right)^q \quad (8.14)$$

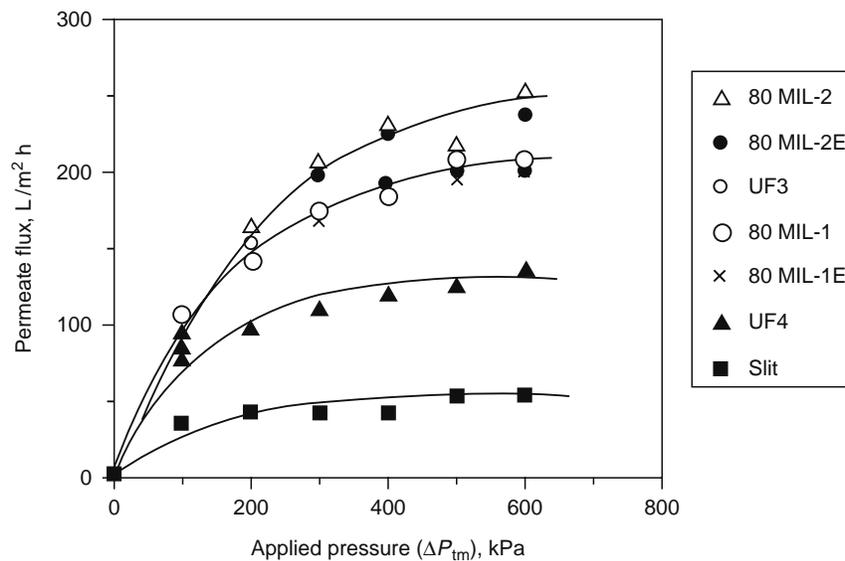

where

$L_s$  is channel length

$d_h$  is the hydraulic diameter

The hydraulic diameter can be calculated by

$$d_h = \frac{4 \times \text{cross section}}{\text{wetted perimeter}} = \frac{4\varepsilon}{2/h_{sp} + (1 - \varepsilon)S_{vsp}} \quad (8.15)$$

**FIGURE 8.14** Flux versus transmembrane pressure for different spacers. (From Figure 4 in Da Costa, A.R. and Fane, A.G., *Ind. Eng. Chem. Res.*, 33, 1845, 1994. With permission.)

where  $h_{sp}$  is the thickness of the spacer. This is equal to the height of the spacer-filled channel, but it is less than  $(d_{f1} + d_{f2})$  because the filaments are slightly embedded in each other. The other dimensionless numbers in Equation 8.14 can be calculated as

$$Sh = \frac{kd_h}{D} \quad (8.16)$$

$$Re = \frac{Vd_h}{\nu} \quad (8.17)$$

$$Sc = \frac{\nu}{D} \quad (8.18)$$

where  $V$  is the superficial channel axial velocity.

The friction factor for channel pressure loss can be related to the Reynolds number by the following empirical correlation:

$$f = \frac{A}{Re^n} \quad (8.19)$$

According to Da Costa and Fane [31], a lower value of  $n$  is indicative of a higher degree of turbulence in the fluid flow.

Table 8.3 shows the experimentally determined coefficients for the mass transfer and the friction coefficient correlations for the spacers shown in Figure 8.13 [32]. The coefficients in Equations 8.14 and 8.19 are highly spacer geometry dependent and different for various arrangements of the spacer in the channel. Da Costa et al. [32] also carried out an illustrative economic analysis on membrane (capital) and energy (operating) costs for the spacers tested based on hypothetical cost parameters. Table 8.3 shows the total costs of different spacer options under conditions of flow rate 3 L/min. Under such a flow condition, it seems that the UF4 was the most efficient spacer compared with the others. However, the total cost of the membrane process would be a function of the crossflow rate. A high crossflow rate can result in a high energy cost but a reduced membrane area because an increased flux should be achieved under high crossflow conditions. This implies that there may be an optimal crossflow rate at which the minimum total cost (i.e., the sum of the operating and capital costs) can be achieved. Figure 8.15 shows the estimated costs versus crossflow for the spacers tested by Da Costa et al. [32]. Given that typical spiral wound elements are usually operated with a crossflow velocity less than 0.6 m/s due to the limitation of the maximum pressure drop across the elements to avoid telescoping, the 80 MIL design could be the optimal spacer in this set of spacer designs for a practical crossflow range.

While the average mass transfer in a space-filled channel can be experimentally related to the spacer configuration and the average flow conditions, computational fluid dynamics (CFD) can be used to analyze the details of the local hydrodynamic characteristics and the wakes formed behind the filaments. Figure 8.16 shows the results of CFD simulations of the local flow patterns in a spacer-filled channel with the cavity, zigzag, and submerged spacer arrangements [33]. The simulations indicate that large recirculation regions may be formed behind the filaments and the shed vortices can scour the channel wall and enhance the shear stress at the membrane surface. For the cavity geometry spacer, the recirculation regions between sequential filaments influence each other and merge to form one large recirculation region between sequential filaments above a critical Reynolds number or below a critical mesh length. In contrast, the zigzag spacers forced the channel flow into an up-and-down zigzag pattern, which caused the recirculation region to reattach to the wall.

Figure 8.17 shows experimental data for the typical particle deposition pattern in a spacer mesh with one filament orientated perpendicular to the main flow direction and the other filament parallel with the main flow. The deposition was recorded using a technique called DOTM [33]. The observation shows that there is a clear area with negligible deposition on the membrane behind and in front of the transverse filaments due to the effect of the inertial force and the scouring of the eddies. The clear area was observed to increase with increase in the crossflow velocity. Using the DOTM technique, Neal et al. [34] measured the effect of spacers on the critical flux of small particles and found that critical fluxes were enhanced by up to twice that of an empty channel. In summary, the flow channel spacers used in the popular SWM significantly enhance flux and performance for feeds with both dissolved solutes and particulates. The penalty is increased pressure loss. This leads to an optimal design and operating range that minimizes the processing costs.

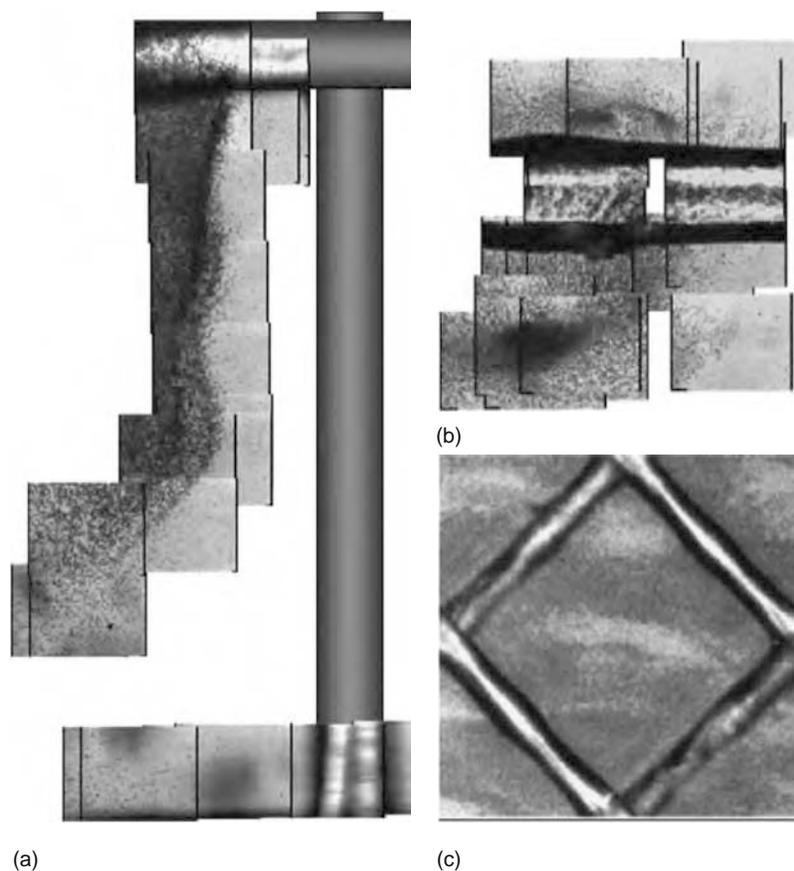

### 8.3.2 OTHER TURBULENCE PROMOTERS

#### 8.3.2.1 Helical Inserts

Figure 8.18 shows a typical design of a winding helical insert that is centrally located in a tubular membrane. This type of insert can be easily fabricated by winding a metal or plastic wire onto a rod. The main structural parameters of this insert include

**FIGURE 8.16** CFD simulation for unsteady flow for  $Re = 1200$  for the (a) cavity, (b) submerged, and (c) zigzag spacer at a fixed mesh length and filament diameter. (From Figure 16 in Schwinge, J., Neal, P.R., Wiley, D.E., Fletcher, D.E., and Fane, A.G., *J. Membr. Sci.*, 242, 129, 2004. With permission.)

**FIGURE 8.17** DOTM revealed particle deposition pattern for different spacer orientations (a–c). (From Figure 13 in Schwinge, J., Neal, P.R., Wiley, D.E., Fletcher, D.E., and Fane, A.G., *J. Membr. Sci.*, 242, 129, 2004. With permission.)

the rod diameter, pitch, and the clearance distance between the tubular membrane and the insert. Flow visualization shows that the presence of the helical baffle in the tubular membrane induces a rotational flow within the baffle and the angle of rotation depends on the pitch or the number of turns over the length of the baffle. Three flow components were identified, which are the tangential flow in the clearance between the membrane and the insert, the rotational helical flow following the shape of the helical, and a reverse flow generated by the secondary flows on the cylindrical rod surface [35]. The flow near the membrane surface is dominated by tangential and rotational flows. It was reported that no obvious vortices were observed in the tube with helical inserts even at relatively high flow rate.

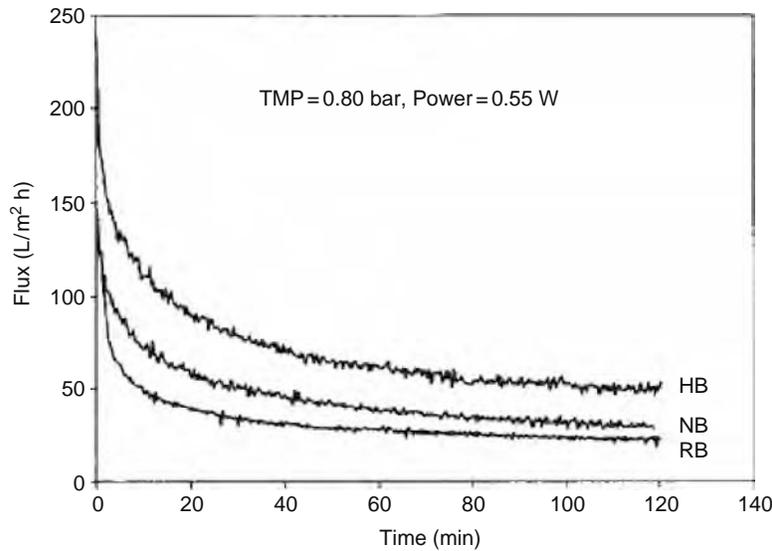

Figure 8.19 shows the flux-time profiles obtained in filtration of 5% yeast cell suspension using a tubular membrane of 6 mm i.d. (inside diameter) and 0.14  $\mu\text{m}$  pore size with a helical baffle (HB), a rod baffle (RB), and the tubular membrane without baffle (NB) [35]. The comparison has been made at the same hydraulic-dissipated power, which is defined as the product of the flow rate and the pressure drop along the tubular membrane, or the energy consumed to generate the crossflow through the tubular membrane. Using the hydraulic-dissipated power rather than the crossflow rate as a control parameter for the comparison of the tubular membrane with and without inserts eliminates the effect of the reduced crossflow section by

Main types of flow

- Perimeter component
- Helical component
- Reverse flow

**FIGURE 8.18** Schematics of a helical baffle. (From Figure 2 in Gupta, B.B., Howell, J.A., Wu, D., and Field, R.W., *J. Membr. Sci.*, 102, 31, 1995. With permission.)

**FIGURE 8.19** Flux-time profiles for filtration with HB, RB, and NB modes. (From Figure 4 in Gupta, B.B., Howell, J.A., Wu, D., and Field, R.W., *J. Membr. Sci.*, 102, 31, 1995. With permission.)

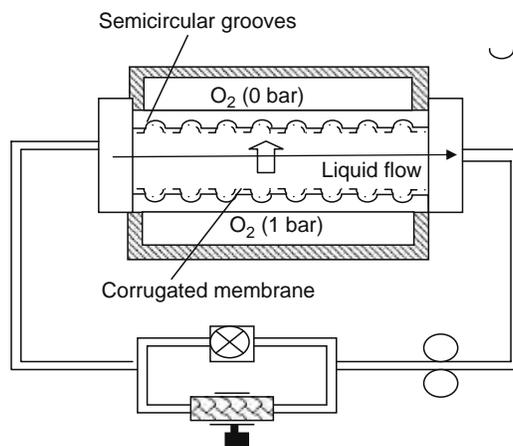

introduction of the inserts. From Figure 8.19, it can be seen that the presence of the helical baffle resulted in a higher flux, but the flux with the RB mode was slightly lower than the NB mode. The rod-type baffle (RB mode) has a similar parallel flow pattern to the NB mode but the value of the tangential velocity is lower than that with the NB mode for a given hydraulic-dissipated power. This explains the slightly lower flux with the RB mode. The enhancement of filtration performance by helical baffles was also reported in the filtration of different difficult feeds using tubular membranes, including crude oil emulsions and mixtures of crude oil with biological solids from activated sludge processes [36], dextran T500 [37], and municipal wastewater [38].

One of the important characteristic parameters of the helical inserts is the pitch, or the turns per unit length. A large pitch means fewer turns of the helices over a certain length of the baffle. However, the limit of indefinitely increasing the number of turns or reducing the pitch will be a geometry approaching a rod-type baffle with negligible rotational flow. Thus there should be an optimal number of helices for flux enhancement. Gupta et al. [35] experimentally determined that a helical baffle made up of four turns per 25 mm length was optimal, which is similar to the optimal 5 mm pitch determined by Xu et al. [38]. Gupta et al. [35] also suggested that a gap of about 1 mm between the membrane inner surface and the baffle height is appropriate for good filtration performance using this type of baffle.

### 8.3.2.2 Corrugated Membranes

Corrugated membranes have been tested and were formed by spreading flat sheet membranes over a corrugated supported plate. The corrugated structure of the plate was made by half-cylindrical bars attached to or grooves machined into the plate [39,40]. The depth of the semicircular bar or groove could be from less than 1 mm to several millimeters. van der Waal and Racz [39] studied the effect of corrugations on filtration with 3 mm circular bars glued onto the support plate. Flow visualization revealed that the membrane corrugations resulted in a transition from laminar to turbulent flow at a lower velocity than with a flat membrane. Circulation eddies formed behind the corrugation over a downstream distance up to about 10–15 mm. The filtration experiments indicated that corrugations can result in an enhancement in mass transfer coefficient, provided the separation distance between corrugations was in the range 15–40 mm. However, no significant effects were observed with larger or smaller mutual distances, such as 80 and 10 mm, respectively.

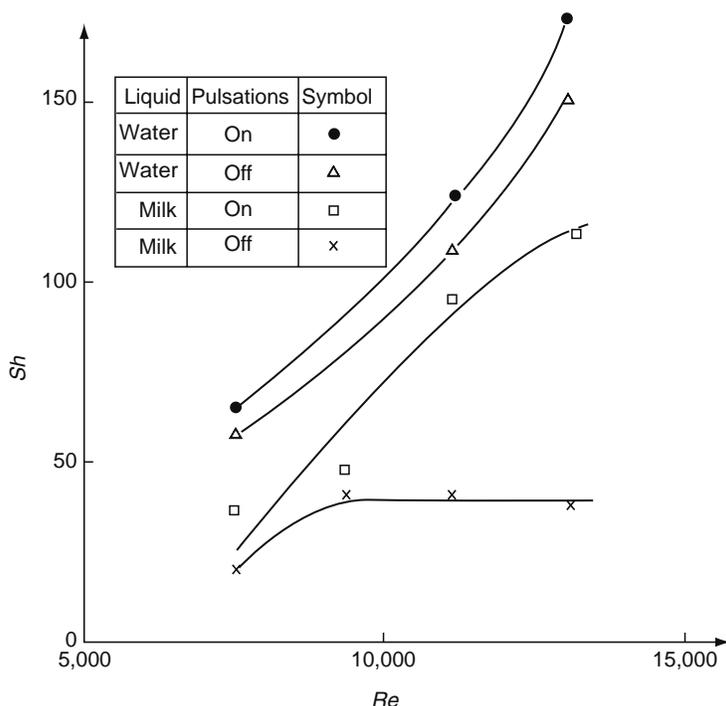

Stairmand and Bellhouse [40] tested the combined effect of corrugated membranes and pulsated flow on mass transfer in a blood oxygenator. Figure 8.20 shows the schematics of the device used in their experiments. The corrugated structure tested by them was formed by semicircular grooves of 0.75 mm depth and 1.25 mm separation, much shallower and more closely spaced than that tested by van der Waal and Racz [39]. The pulsated flow was produced by a rotating 0.5 in. ball that intermittently closed the line and a section of flexible tube, which could be clamped to varying degrees to alter the stroke of the pulsations. During the experiments, the oxygen was convectively transferred from the high pressure chamber (1 bar) to the low pressure chamber (0 bar) through the liquid flowing through the channel between these two chambers. The rate of convective transfer across the channel would depend on the intensity of mixing of the fluid flowing through the channel. Figure 8.21 [40] shows the effect of pulsations on oxygen transfer between the two corrugated membranes with water and milk-filled channels under conditions of different Reynolds number. The experimental data indicate that for nonfouling liquid medium (distilled water)

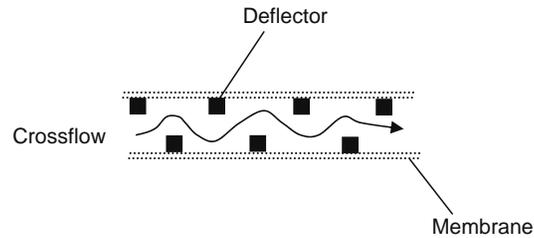

**FIGURE 8.20** Schematics of simulated oxygenator employed with corrugated membrane and pulsatile flow. (Adapted from Figures 1 and 2 of Bertram, C.D., Hoogland, M.R., Li, H., Odell, R.A., and Fane, A.G., *J. Membr. Sci.*, 84, 279, 1993.)

where the Reynolds number exerted a dominant effect on oxygen transfer rate applying an 8 Hz pulsation to the water-filled channel could enhance the Sherwood number by about 20%. For fouling medium (milk-filled channel), the effect of Reynolds number on oxygen transfer could be considerably limited by membrane fouling. However, this phenomenon was found to be partially reversed by the application of pulsations. For Reynolds numbers larger than 10,000, the Sherwood number was enhanced by a factor of about 2 by imposition of pulsations, confirming the effect of pulsations on reducing concentration polarization with corrugated membranes.

Instead of using a furrowed or dimpled membrane support plate, Sobey [41] observed that a single flow deflector in a flat membrane channel could produce many vortices under oscillatory flow conditions, an effect named the “vortex wave.” An important feature of the vortex wave is that it could occur under low crossflow velocity conditions or with laminar flow so that it can be used for shear-sensitive fluids. Millward et al. [42] tested the effect of vortex waves on plasma filtration with waves produced by flow deflectors with cross-sectional area of  $1 \times 1 \text{ mm}^2$  in a 2.25 mm high channel as shown in Figure 8.22. The aim was to improve membrane applications for the separation of plasma from cellular blood components for both donor

**FIGURE 8.21** Effect of pulsatile flow on oxygen transfer with water and milk medium. (From Figure 3 in Stairmand, J.W. and Bellhouse, B.J., *Int. J. Heat Mass Transfer*, 27, 1405, 1985. With permission.)

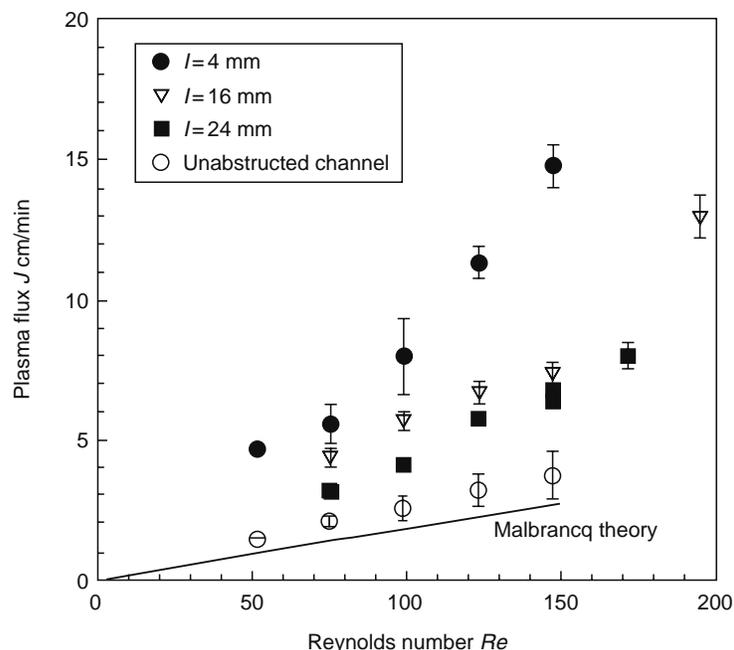

**FIGURE 8.22** Schematics of membrane flow channel equipped flow deflector.

plasmapheresis and the treatment of autoimmune disease. For this application, it is important to achieve a high-plasma filtration rate with negligible damage to the blood components under limited blood flow rate conditions so there would be a need to employ secondary flows to control concentration polarization and membrane fouling. Figure 8.23 shows the plasma flux obtained with different spacings of flow deflector under relatively low Reynolds numbers, in the range of 50–200, using 0.2  $\mu\text{m}$  flat sheet membranes. The results indicate that the addition of narrowly spaced (4 mm) flow deflectors to the membrane channel enhanced the flux significantly by a factor of 3.5 compared to an empty channel at a Reynolds number  $Re = 123$ . More importantly, it was found that the deflectors did not increase the channel pressure drop significantly in such a low Reynolds range. Millward et al. [42] also demonstrated that the oscillatory flow component was an essential feature of the vortex wave design. They found that the plasma flux dropped from 0.1 to 0.01 cm/min by removing the oscillations during the filtration with a channel with 4 mm spaced deflectors. These results demonstrate that significant flux enhancement could be obtained by combining a turbulence promoter and pulsation design even with laminar flow conditions.

## 8.4 PULSED FLOW

### 8.4.1 HYDRODYNAMIC CHARACTERISTICS OF PULSATILE FLOW

Pulsatile flow can be defined as flow with a periodic pressure fluctuation wave travelling along the flow path. As in a steady Poiseuille's flow, it is the pressure gradient along the flow path that determines the instantaneous pulsatile flow rate. For the flow path shown in Figure 8.24, the pressure gradient is determined by the pressure difference between the pressure recorded at upstream point A and that recorded at the downstream point B. Owing to the pressure pulse transfer from the original source of the pulsation down along the flow path, the crest of the wave reaches point A short time before it reaches the downstream

**FIGURE 8.23** Plasma flux obtained with flow deflector-equipped channel with and without pulsation. (From Figure 3 in Millward, H.R., Bellhouse, B.J., Sobey, I.J., and Lewis, R.W.H., *J. Membr. Sci.*, 100, 121, 1995. With permission.)

**FIGURE 8.24** Pulsed flow between two points a short distance apart along a channel.

point B, at this time the pressure at point A is higher than that at point B. A short time later, as the crest reaches at the point B, the pressure at the point B will be higher than that at the point A. Thus, the pressure pulsation will cause a rapid forward-and-reverse pressure gradient oscillation over the flow path AB. Figure 8.25 shows how a travelling sinusoidal pressure waveform creates an oscillatory pressure difference. Figure 8.25a shows two simulated waveforms recorded at two points over a short distance of a flow path with a  $10^\circ$  interval and Figure 8.25b shows the instantaneous pressure gradient between the upstream and the down stream points. From this figure it can be seen, during one period of the pressure fluctuation the pressure gradient over the short flow path also experiences change from a negative to positive value. The motion of the fluid that is driven by an oscillating pressure gradient is complicated. The following momentum equation has been developed for an incompressible laminar pulsatile flow in a circular rigid tube:

$$\frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} + \frac{1}{\eta} \frac{\partial P}{\partial z} = \frac{\rho}{\eta} \frac{\partial w}{\partial t} \quad (8.20)$$

where

$P$  is the pressure

$w$  is the velocity in the axial direction

For steady flow the velocity does not vary with time, so that  $\partial w / \partial t = 0$ . The pressure gradient  $\partial P / \partial z$  can be measured over a finite distance and written as

$$\frac{\partial P}{\partial z} = \frac{P_1 - P_2}{L} \quad (8.21)$$

When the pressure gradient is in the form of single harmonic with complex components

$$-\frac{\partial P}{\partial z} = A^* e^{i\omega t} \quad (8.22)$$

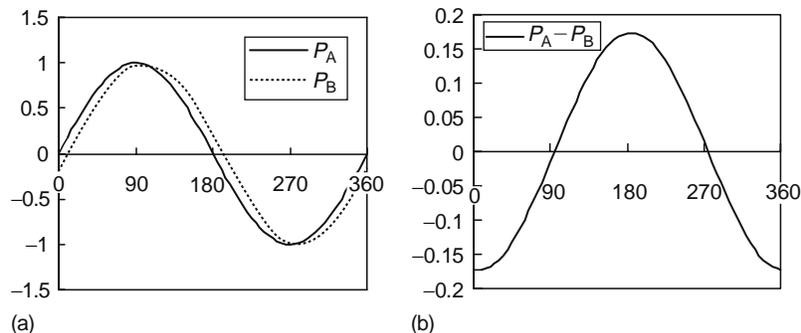

where

$A^*$  is the amplitude of pressure gradient in complex form

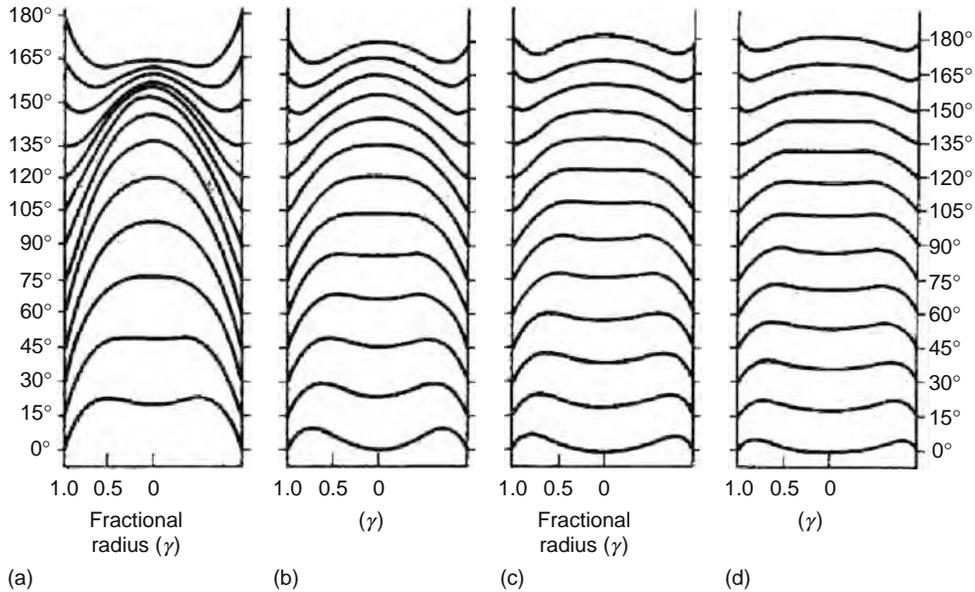

$\omega$  is the angular velocity

For symmetric flow with nonslip conditions applied, the solution of equation is [43]

$$w = \frac{A^* R^2}{i\eta\alpha^2} \left\{ 1 - \frac{J_0(\alpha y l^{3/2})}{J_0(\alpha l^{3/2})} \right\} e^{i\omega t} \quad (8.23)$$

**FIGURE 8.25** Waveform of pressure difference. (a) Two simulated waveforms recorded at two points over a short distance of a flow path with a  $10^\circ$  interval and (b) instantaneous pressure gradient between the upstream and the down stream points.

**FIGURE 8.26** The velocity profiles of the flow resulting from a sinusoidal pressure gradient ( $\cos \omega t$ ) in a tube. (a)  $\alpha = 3.34$ , (b)  $\alpha = 4.72$ , (c)  $\alpha = 5.78$ , and (d)  $\alpha = 6.67$ . (From Hale, J.F., McDonald, D.A., and Womersley, J.R., *J. Physiol.*, 128, 629, 1955. With permission.)

where  $J_0(\alpha i^{3/2})$  is a Bessel function of the first kind of order zero and complex argument,  $y = r/R$ . The parameter  $\alpha$  is a dimensionless number that characterizes the kinematic similarities in the liquid motion, known as the Womersley number. It is written as

$$\alpha = R(\omega/\nu)^{1/2} \quad (8.24)$$

The volume flow can be obtained by integrating the velocity across the lumen of the tube:

$$Q = \frac{\pi A^* R^2}{i\omega\rho} \left\{ 1 - \frac{2J_1(\alpha i^{3/2})}{\alpha i^{3/2} J_0(\alpha i^{3/2})} \right\} e^{i\omega t} \quad (8.25)$$

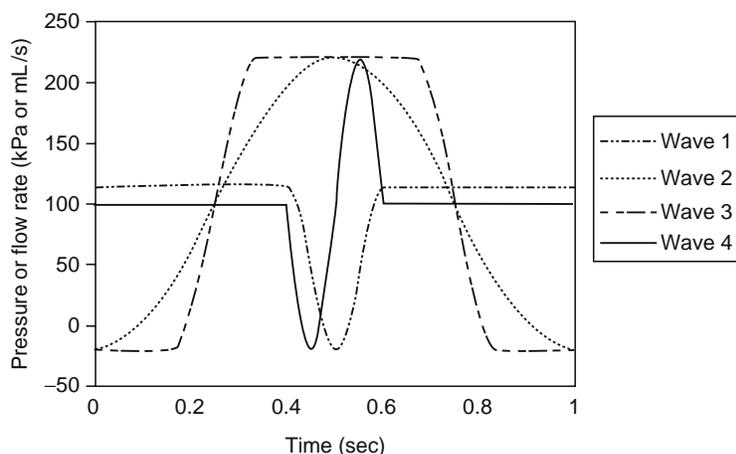

where  $J_1$  is Bessel function of order one.

The velocity profile across the tube lumen with pulsatile flow is not of the same parabolic form as that found in a steady laminar flow. The velocity profiles oscillate sinusoidally as discussed in detail by Hale et al. [44]. For example, Figure 8.26 shows the velocity profiles, at intervals of  $15^\circ$ , resulting from a simple sinusoidal pressure gradient ( $\cos[\omega t]$ ) during the half cycle ( $0^\circ$ – $180^\circ$ ); as for a simple harmonic motion, the second half is the same.

It can be seen from Figure 8.26, for a pulsed pressure gradient, the characteristic parabolic velocity profile observed in steady laminar flow does not appear at any time during the cycle. There is a phase lag between the pressure gradient and the liquid movement, and being a cosine function, the maximum amplitude of the pressure gradient occurs at  $0^\circ$ , while the maximum for the total flow is at  $60^\circ$  in Figure 8.26a and at about  $70^\circ$  in Figure 8.26b. Significant shear is found only in the region near the wall with the liquid in the central portion of the tube virtually unshered. Thus, the liquid behavior for pulsatile flow is rather like a solid mass sliding inside a thin layer of viscous liquid surrounding it. The higher the Womersley number (the higher the frequency or the larger the tube diameter), the flatter is the velocity profile, implying a thinner boundary layer at higher Womersley number.

#### 8.4.2 PULSATILE FLOW-ENHANCED MEMBRANE PROCESSES

Two mechanisms, shear-related and oscillated backflushing, have been suggested for pulsatile flow-enhanced membrane processes by Li et al. [45]. The shear-related mechanisms contribute to the filtration enhancement by a reduced boundary layer and enhanced particle back transport. Since the shear scouring effect is not direction dependent, the maximum absolute value of the shear may be used to estimate the limiting or critical flux for filtration under certain conditions. For laminar flow, the wall shear can be calculated based on the Womersley equation (Equation 8.24). For turbulent flow, there is no simple solution for the wall shear next to the membrane surface. Li [46] suggested estimating the wall shear based on the measured pressure gradient with the assumption that the same pressure gradient should also apply to the boundary layer.

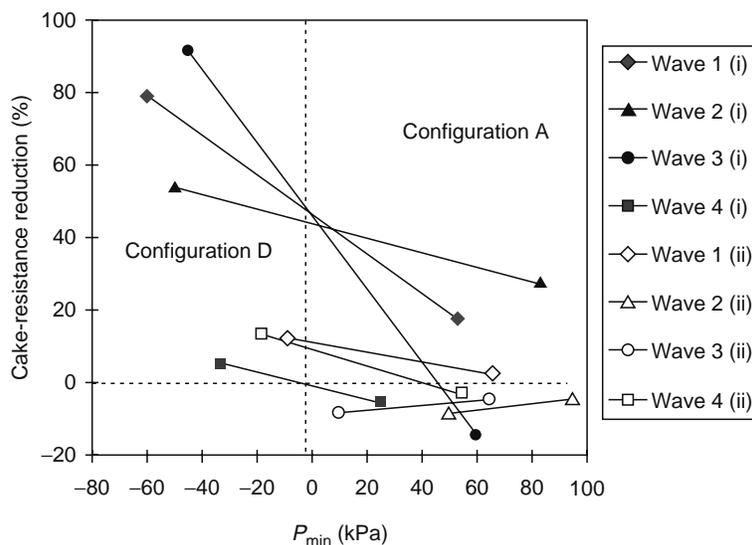

**FIGURE 8.27** Design waveform for pressure and flow rate. (From Figure 2 in Li, H. and Bertram, C.D., *AIChE J.*, 44, 1950, 1998. With permission.)

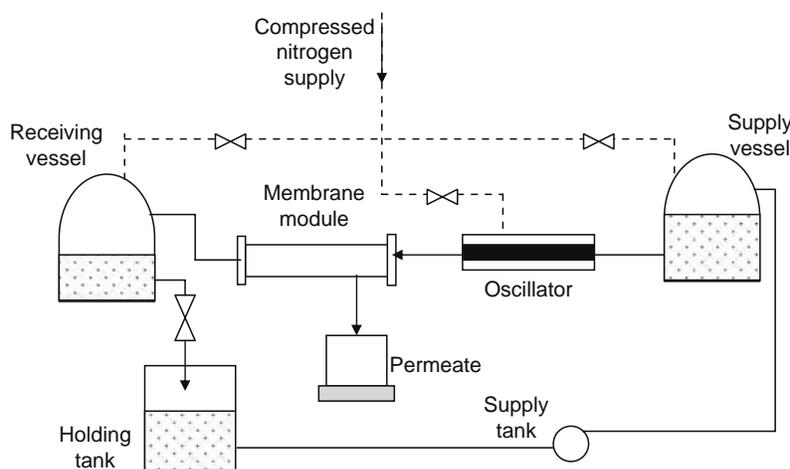

Thus, the maximum shear can be regarded as being proportional to the maximum absolute pressure gradient along the membrane module [46].

The oscillated backflushing mechanism accounts for the effect of the pressure waveform on TMP. When the minimum pressure of the pulsatile pressure waveform results in a negative TMP, a reverse permeate flow may occur that acts as a backwash flow that drives particles deposited on or near the membrane surface back to the bulk flow. In this way, concentration polarization and cake formation caused by the filtration operation could be limited, depending on the properties of the particles and the magnitude of the reverse pressure.

To obtain oscillated backflushing and enhanced membrane performance, the design of the pressure waveform is crucial. The pressure waveform can be characterized by the minimum and maximum pressure, the duration of the negative pressure and the positive pressure, and the pulsation frequency. Figure 8.27 shows four typical pressure waveforms studied by Li [46]. Wave-type 1 has a long steady-pressure phase and a short negative pulsation. Wave-type 2 has an approximate sinusoidal form with smooth variation of the pressure. Wave-type 3 is approximately square shaped and wave-type 4 had a shortened sinusoidal disturbance. Figure 8.28 shows the cake-resistance reduction results as a function of the minimum TMP obtained by Li et al. [45] for pulsatile flow filtration with the four pressure waveforms shown in Figure 8.27 for two amplitudes. It can be seen from Figure 8.28 that a significant reduction in cake resistance in filtration of 0.5 g/L silica suspension using a ceramic membrane of 0.2  $\mu\text{m}$  was obtained by using waveform-type 1 and 3 with relatively large negative TMPs. Waveform-type 1 had a long steady-pressure phase and a short, negative low pressure pulse which may result in a short period backflushing. For this waveform-type about 80% reduction in cake resistance was achieved when the minimum TMP was reduced to about  $-60$  kPa.

**FIGURE 8.28** Cake-resistance reduction with different waveform-type designs. (From Figure 9 in Li, H. and Bertram, C.D., *AIChE J.*, 44, 1950, 1998. With permission.)

**FIGURE 8.29** Schematics of the filtration setup with collapse-tube pulsation generator. (Adapted from Figure 1 of Bertram, C.D., Hoogland, M.R., Li, H., Odell, R.A., and Fane, A.G., *J. Membr. Sci.*, 84, 279, 1993.)

The waveform-type 3, which had a longer negative pressure period than waveform-type 1, resulted in more than 90% reduction in filtration resistance with a minimum TMP of about  $-40$  kPa, implying the effect of duration of the backflushing. Waveform-types 3 and 4 were long and short sinusoidal forms, providing a continuous variation of pressure. There seemed to be less effective reduction in cake resistance with the shorter negative pressure period (waveform-type 4).

Pulsated flow can be achieved by various flow control methods. Figure 8.29 shows a lab-scale membrane filtration setup with the so-called collapsible-tube oscillator used by Bertram et al. [47] for producing pulsated flow in membrane filtration. This system included a supply vessel, a membrane module, a receiving tank, a holding tank, and the collapsible-tube oscillator. The collapsible-tube oscillator consisted of a horizontally mounted 365 mm length of silicone rubber tube with unstressed inside diameter 13.2 mm and wall thickness 3.2 mm, clamped at each end by stainless steel fittings. The pulsations with this device are produced by periodic collapse and reopening of the tube induced by pressure applied to the chamber surrounding the tube. With this arrangement the frequency of the pulse flow can be controlled in a range of 7–12 Hz, depending on the volume of fluid downstream being oscillated, tube parameters, and pressure manipulation.

Many researchers have assessed the effect of pulsatile flow on different membrane processes with wide range of feeds. One of the first studies was by Kennedy et al. [48] who showed that flux in the RO of sucrose solution could increase by 70% by pulsatile flow at 1 Hz. Gupta et al. [49] reported a 45% enhancement of flux in MF of raw apple juice with a pressure waveform provided by a fast piston return followed by a fast forward stroke at 1 Hz. Jaffrin [50], using hollow fiber filters, demonstrated a 45% enhancement in flux in plasma filtration. Using the collapsible-tube oscillation generator described above, Bertram et al. [47] demonstrated that pulsation resulted in a 60% increase in permeate flux in the filtration of silica suspensions.

### 8.4.3 TRANSMEMBRANE PRESSURE BACKSHOCK TECHNIQUE

Instead of exerting pressure pulsing on the feed side, Rodgers and Sparks [51] tested periodic pressurization of the filtrate from 5 to 30 kPa above the respective operating pressure to obtain pulsatile negative TMBs. With a short period of negative pressure or backshock (0.01–0.38 s) presented at a frequency of 0–5 Hz, their experiments showed average increase in permeate flux of 62%–174% for ultrafiltration of 1% bovine serum albumin (BSA) solutions with laminar crossflow. However, no improvement in flux was observed with turbulent flow as a result of TMP pulsing. Guerra et al. [52] assessed the effect of backshock on the filtration of skim milk using so-called normal and reverse asymmetric membranes. The normal asymmetric membrane refers to the asymmetric membrane with the tight skin of the membrane facing the feed (as is usual practice). The reverse asymmetric membrane was with the porous support layer facing the feed. Guerra et al. [52] reported that for filtration with the normal asymmetric membrane, the permeate flux could be increased by 100% by applying a backshock of 0.022 s at a frequency 0.33 Hz for the filtration of skim milk. For filtration with the reverse asymmetric membrane without backshock, it was found that concentration polarization formed within the porous support layer and it was impossible to filter skim milk with such a flow arrangement. However, with backshock, the imposed flux in filtration of skim milk with reverse asymmetric membrane was able to be stepped up to higher than  $350 \text{ L/m}^2 \text{ h}$  without resulting in a significant increase in TMP at a crossflow velocity of 1 m/s; an immediate decrease was observed after the backshock was stopped [52]. This combination of reverse asymmetric membranes and backshock has been patented [53].

Another reported application of backshock is in filtration using membranes called microsieves, which are very thin and smooth membranes with uniform pores made by silicon micromachining [54]. The thinness (ca.  $1.2 \mu\text{m}$ ) and high porosity of

microsieves can result in a high flux in the order of  $10^4 \text{ L/m}^2 \text{ h}$  even under very low TMP conditions. However, such a high flux could result in the rapid formation of a cake layer on the membrane surface within a fraction of a second. To control the cake formation caused by high flux, TMP pulsation is usually applied in filtration by microsieves. Kuiper et al. [55] reported that the cake layer formed by yeast particles in microsieving filtration of lager beer could be largely prevented by applying a backflush of  $-0.05 \text{ bar}$  with a pulse duration  $0.05 \text{ s}$  at a frequency of the order of seconds. Moreover, direct observation revealed that the backpulse could lift particles that stayed on the membrane surface after backflushing off the surface. These loosely attached particles or flocs were found to be eventually removed by a sudden increase in the crossflow velocity for a short period.

The efficiency of backshock can be assessed based on the ratio of the filtrate volume obtained during the filtration period to the volume of permeate lost during the backshock period in a working cycle. The ratio of gained and lost filtrate volume is a function of backflush frequency, the period of backflushing, the operation conditions, and the properties of the foulant materials. A high-operational flux usually needs a strong backflush, which may correspond to an increased loss of permeate volume, to maintain stable performance. Therefore, the backflush conditions need to be optimized to maximize the productivity of the process.

## 8.5 HIGH SHEAR DEVICES

In conventional crossflow filtration, the shear on the membrane surface is usually produced by the feed flow driven by a pump. The shear rate can get up to the order of  $10^4 \text{ s}^{-1}$ . High liquid flow results in high pressure drop along the membrane module, leading to considerable energy consumption and nonuniform distribution of TMP over the flow path of the feed channel. Such a close dependence between high crossflow velocity and pressure drop limits the use of high crossflow in various commercial membrane modules. However, in high shear membrane filtration devices, the relative movement between the liquid and the membrane surface is induced by an independent device rather than a liquid transport pump. With shear rate independent of the feed bulk flow, the high shear membrane filtration devices can be operated at a relatively homogeneous and controllable TMP. The typical high shear membrane filtration devices include rotating disks and vibrating dynamic membrane filtration systems, as described below.

### 8.5.1 ROTATING SYSTEMS

Figure 8.30 shows the typical structure of a rotating dynamic membrane system which consists of a stationary flat membrane, a rotating disk, a hollow shaft, and a cylindrical housing with feed inlet and permeate outlet. During filtration, the feed is pumped into the closed housing, flowing through the membrane and evacuating through the hollow shaft. The permeate flow comes out of the system from the permeate outlet. Driven by an electric motor, the rotating disk rotates at high speed ( $100\text{--}1000 \text{ s/rpm}$ ) to produce shear on the membrane surface. The TMP can be controlled by a valve in the retentate outlet line.

The centrifugal forces generated by the disk induce an outward radial flow near the rotating disk and inward radial flow toward the axis near the membrane surface. If there is a relative large gap (several millimeters) between the membrane and the rotating disk, the flow in the gap can be approximately treated as a flow core that rotates at an angular velocity of  $k\omega$  between two boundary layers on the membrane and the rotating disk surface, where  $\omega$  is the rotating velocity of the disk and  $k$  is a coefficient between 0.3 and 0.44 [56]. The azimuthal Reynolds number can be defined as  $Re = k\omega R/\nu$ . The shear on the membrane surface at radius  $r$  can be calculated based on the expressions for different flow regimes [57].

Laminar boundary layer regime,  $Re < 2.5 \times 10^5$ ,  $e/R > 0.05$  (where  $e = \text{gap height}$  and  $R = \text{radius}$ )

$$\gamma = \frac{0.77(k\omega)^{3/2}r}{\nu^{1/2}} \quad (8.26)$$

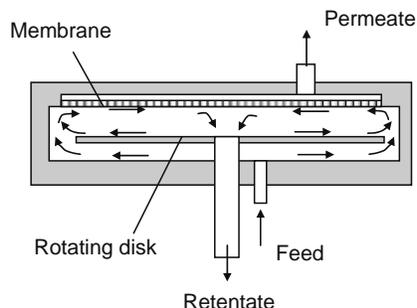

FIGURE 8.30 Schematic diagram of rotating disk dynamic membrane filter.

In the turbulent regimes ( $Re > 2.5 \times 10^5$ ,  $e/R > 0.05$ ),

$$\gamma = \frac{0.0296(k\omega)^{9/5}r^{8/5}}{\nu^{4/5}} \quad (8.27)$$

Typically, for a disk with diameter 150 mm rotating at speeds of 500 or 2000 rpm, the calculated shear rates at the edge of the disk based on Equation 8.27 with  $k=3.7$  are  $6.4 \times 10^3$  and  $7.7 \times 10^4 \text{ s}^{-1}$ , respectively.

The pressure in the gap is also a function of the radius distance. The radial gradient in the boundary layer is equal to that in the inviscid core as given by [56]

$$\frac{\partial P}{\partial r} = \rho r(k\omega)^2 \quad (8.28)$$

The pressure distribution can be obtained by integrating Equation 8.28 from  $r=0$  to  $r$ , assuming  $k$  is independent of  $r$ .

$$P = \frac{1}{2}\rho(k\omega r)^2 + p_0 \quad (8.29)$$

For a rotating disk dynamic membrane filter, the TMP and the shear rate on the membrane surface vary radially as indicated by the above equations. Bouzera et al. [56] studied the averaged filtration resistance at different radial zones for different rotating speeds using calcium carbonate particle (mean diameter 4.7  $\mu\text{m}$ ) suspension as the model fluid. In the experiments, several Nylon membranes were partially sealed with epoxy to obtain membranes with different centric permeable zones:  $r < 3$ ,  $3 < r < 4.5$ ,  $4.5 < r < 6$ , and  $6 < r < 7.5$  cm. The results indicated that for the filtration zones  $r > 3$  cm, the resistance is equal to the membrane resistance for all the rotating speeds  $\geq 200$  rpm, implying that the particle deposition can be effectively arrested by a rotating speed as low as 200 rpm in this membrane zone. For the center filtration zone ( $r < 3$  cm), the filtration resistance was a strong function of the rotating speed, and the filtration resistance became equal to the membrane resistance only at 2100 rpm, at lower rpm the filtration resistance was greater. Jaffrin et al. [57] reported that the permeate flux of the rotating disk can be significantly enhanced by equipping the rotating disk with radial vanes of a certain height, which can increase the shear rate on the membrane surface considerably.

The following empirical relationship has been suggested to correlate the filtration flux to the shear rate for filtration with a rotating disk dynamic membrane filter:

$$J = A\gamma_m^n \quad (8.30)$$

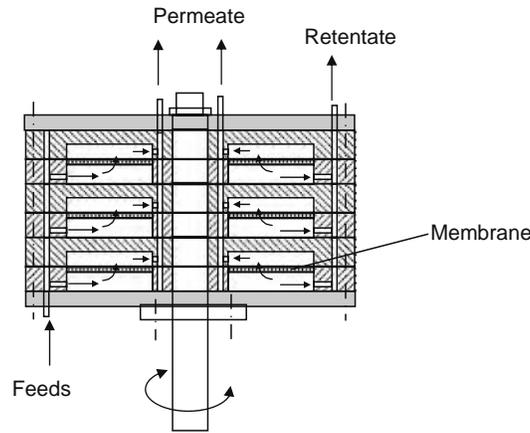

$A = 1$ ,  $n = 0.5$ , and  $A = 0.30$ ,  $n = 0.55$  were suggested for filtration of silica suspension [58] and skim milk [59], respectively.

Several commercially available rotating disk dynamic membrane systems have been tested for different applications. The CR (cross-rotational) system (Radisio-Flootek, Finland, Northern Europe) is multistage with 50 cm diameter disks, providing a total membrane area up to 20  $\text{m}^2$ . It has been tested by Nuortula-Jokinen and Nyström [60] for concentrating paper-mill effluents at a rotor-tip azimuthal velocity of 13 m/s. The SpinTek ST II module (SpinTek, Huntington Beach, California), which can reach an azimuthal velocity of 20 m/s at the tip, has been tested for filtration of oil-water microemulsions with a 500  $\text{cm}^2$  membrane area module [61]. The DMF module (Pall Corp., New York) consists of several disks mounted on the same shaft, such that each can rotate between two annular membranes with maximum rotation speed of 3450 rpm, corresponding to an azimuthal velocity of 20 m/s at the disk tip. Pall's lab-scale system has been tested for protein separation [62] and filtration of recombinant yeast cells [63]. The reported studies of the application of the rotating disk dynamic membrane indicate that high shear-induced filtration is much less sensitive to the solids concentration. High concentration factors achieved at significantly higher fluxes than the conventional processes have been reported with quite a range of feeds, including ferric hydroxide, yeast suspension, and skim milk, etc. [56,59,64].

## 8.5.2 VIBRATORY SYSTEMS

### 8.5.2.1 Vibratory Shear-Enhanced Process

The concept of the vibratory shear-enhanced process (VSEP) (New Logic International, Emeryville, California), proposed by Armando et al. [65], came with the idea to combat concentration polarization and membrane fouling by directly moving the membranes rather than by moving the liquid. The VSEP system consists of a stack of parallel circular membranes mounted in a cylindrical housing which is spun in torsional oscillation at a resonant frequency of about 60 Hz as shown in Figure 8.31.

**FIGURE 8.31** Schematic diagram of vibrating flat sheet membrane module.

The shear rate at the VSEP membrane is created by the inertial-induced relative motion of the fluid, and can be of the order  $10^5 \text{ s}^{-1}$ . The shear rate varies sinusoidally and increases proportionally with local membrane azimuthal displacement to radius. The maximum shear rate at the periphery can be related to the vibrating frequency ( $F$ ) and the membrane displacement at the periphery ( $d$ ) by the following equation [66]:

$$\gamma_{\max} = 1.414d(\pi F)^{3/2} \nu^{-1/2} \quad (8.31)$$

In VSEP,  $F = 60.75 \text{ Hz}$ ,  $d = 3 \text{ cm}$ , so for water-like liquids the value of  $\gamma_{\max}$  is about  $1.1 \times 10^5 \text{ s}^{-1}$ .

The mean shear rate obtained by averaging the absolute value of shear rate over a period and over the membrane area which, for VSEP, is an annular region with radii  $R_1$  and  $R_2$ , can be formulated as

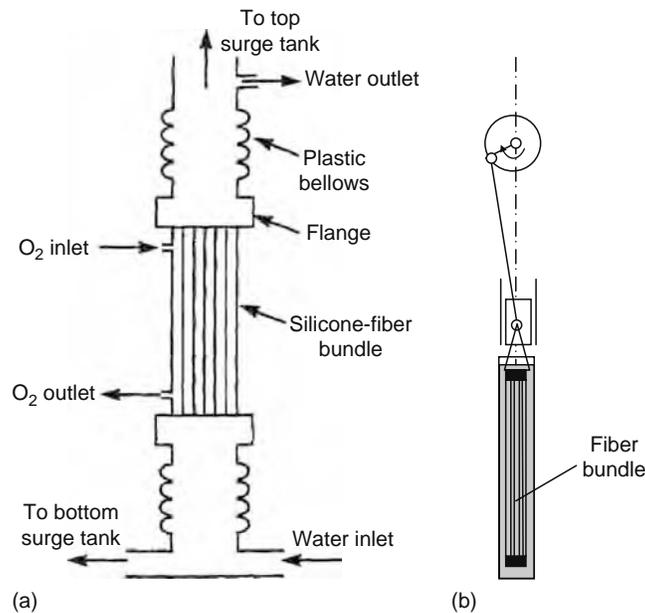

$$\bar{\gamma} = \frac{2.828(R_2^3 - R_1^3)}{3\pi R_2(R_2^2 - R_1^2)} \gamma_{\max} \quad (8.32)$$

Jaffrin et al. [57] have made a hydrodynamic comparison between the rotating disk and the VSEP system based on the flux achieved under similar maximum shear rates for baker's yeast microfiltration with an  $0.2 \mu\text{m}$  MF and skim milk UF at 50 kDa. They found that the flux variation with time in these two modules was nearly identical when they were operated at the same maximum shear rate, suggesting the dominant effect of shear rate on the filtration performance.

### 8.5.2.2 Vibratory Hollow Fiber Membranes

While VSEP demonstrated that vibrations can be applied to flat sheet membrane to enhance membrane filtration, the effect of vibrations on the performance of hollow fibers has also been investigated by a number of researchers for different separation processes. Krantz et al. [67] designed the system shown in Figure 8.32a to assess the effect of axial membrane vibrations on mass transfer in a hollow fiber oxygenator. In this system, a shell and tube silicon fiber module was mounted vertically and connected to the liquid flow inlet and outlet lines via flexible bellows couplings. The membrane module was rigidly attached to the plate of an electromechanical shaker, which could axially vibrate the hollow fiber module over a frequency range from 6 to 18 Hz with an amplitude range of 0.05–1.2 cm. Surge tanks were employed on the liquid inlet and outlet lines to eliminate liquid pressure pulsation in the fiber lumen. The experimental results showed that a maximum enhancement of 1.58 in the Sherwood number ratio was achieved for oxygen transfer to water when the surge tanks were employed to suppress liquid pulsations in the fiber lumen. Without the surge tanks, the vibrations were even more effective and caused a secondary flow in the fiber lumen so that the combined effect of the vibrations and secondary was to increase the enhancement factor to 2.65.

Figure 8.32b shows a vibrating submerged hollow fiber membrane system for filtration applications [68]. In this system, the submerged membrane is vibrated by a mechanical device, which converts the rotating motion of the electric motor to vertical oscillations of the vertical fiber bundles. The system can be operated in a frequency range of 1–10 Hz with a maximum displacement of 4 cm. Figure 8.33 shows the experimentally determined relationship between critical flux and the vibration frequency for filtration of 5 g/L baker's yeast suspensions, indicating a nearly monotonic increase in critical flux with increase in the vibration frequency over the frequency range tested.

**FIGURE 8.32** Schematic diagram of (a) vibrating hollow fiber membrane. (From Figure 5a in Krantz, W.B., Bilodeau, R.R., Voorhees, M.E., and Elgas, R.J., *J. Membr. Sci.*, 124, 283, 1997. With permission.) and (b) vibrating submerged hollow fiber membrane. (From Genkin, G., Waite, T.D., Fane, A.G., and Chang, S., *J. Membr. Sci.* 281, 726, 2006.)

## 8.6 TWO-PHASE FLOWS

Another strategy to provide additional shear or flow instability in the boundary layer is the use of two-phase flow. Two approaches have been applied to membrane processes: bubble addition for gas–liquid two-phase flow and particle addition for solid–liquid two-phase flow.

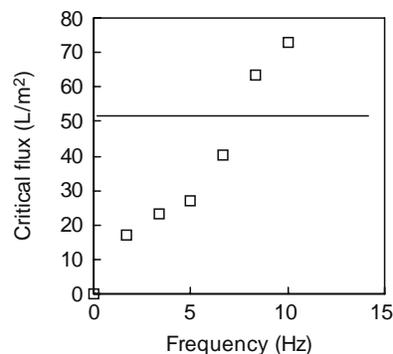

### 8.6.1 GAS–LIQUID TWO-PHASE FLOW

Over the past decade, there has been an upsurge of interest in the use of gas bubbles to enhance membrane processes. The typical applications include two-phase flow filtration with tubular membranes and submerged membrane systems. A major stimulus for the latter has been the development of MBRs.

#### 8.6.1.1 Two-Phase Flow Filtration with Tubular Membranes

As depicted in Figure 8.34, the flow patterns formed in a vertical tube follow a trend with increasing gas flow of bubble flow, slug flow, churn flow, and annular flow. These regimes are described briefly below.

- **Bubble Flow:** the gas phase is approximately uniformly distributed in the form of discrete bubbles in a continuous liquid phase.
- **Slug Flow:** most of the gas is located in large bullet-shaped bubbles, which have diameters almost equal to the tube diameter and are sometimes designated as Taylor bubbles. They move uniformly upward and are separated by liquid

**FIGURE 8.33** Experimentally determined critical flux for filtration of 5 g/L yeast using vibrating hollow fiber membrane.

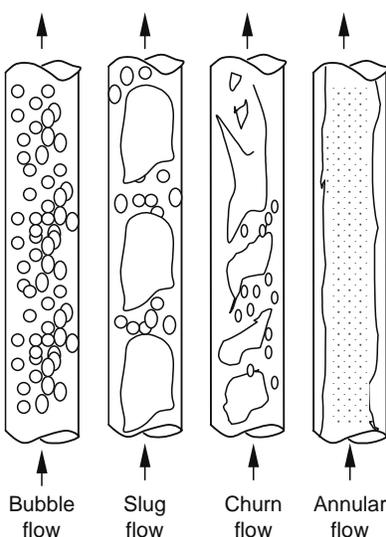

FIGURE 8.34 Flow pattern of gas–liquid two-phase flow in a tubular duct.

slugs which may contain small gas bubbles. Around the Taylor bubbles, there is a thin liquid falling film which causes turbulence in the wake of the Taylor bubble.

- Churn Flow: is somewhat similar to slug flow but is more chaotic, frothy, and disordered.
- Annular Flow: is characterized by the continuity of the gas phase along the core of the tube. The liquid phase moves upward partly as wavy liquid film and partially in the form of drops entrained in the gas flow.

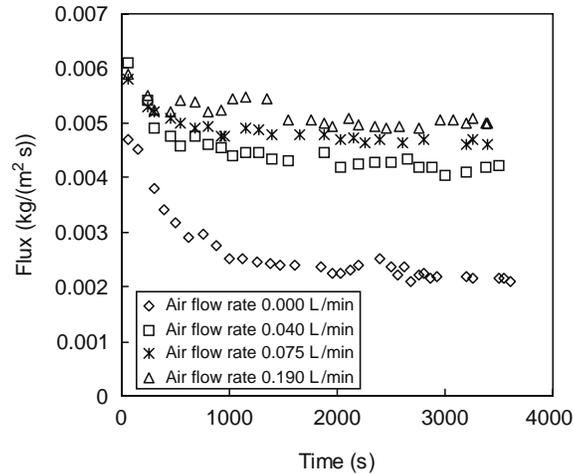

The flow pattern depends on the gas and liquid flow rate as well as the diameter of the duct [69]. For two-phase flow filtration, the flow path for the gas–liquid mixture is relatively narrow and the liquid velocity is usually set at a low value, so the prevalent flow pattern for two-phase flow filtration would be slug flow. When the bubble size reaches about 60% of the tube diameter, the bubble can be categorized as a slug with its characteristic bullet-shaped nose. The rising velocity of the slug depends on the tube size. For tubes of above 10 mm diameter ( $d_b$ ) with a slug length  $1.5d_b$  or above, the rising velocity of bubble can be calculated by

$$U_b = 0.35(gd_b)^{1/2} \quad (8.33)$$

If the tube diameter is less than 10 mm, the liquid surface tension will affect the slug velocity and simulation predicts that for diameters less than about 5 mm with water the surface tension can stop the upward motion of the slug causing an air lock, implying careful assessment is required before applying bubbling to the lumen of hollow fiber membranes.

Many studies have been carried out to evaluate the effect of injection of air into the lumen of tubular and hollow fiber membranes on the performance of membrane filtration. Figure 8.35 shows the filtration results obtained by Cui et al. [70] using a vertically installed tubular membrane module (12.7 mm i.d., PVDF, MWCO: 100 kDa) with dextran solution (MW: 87 kDa) as the test media. As can be seen, injecting gas bubbles, even at quite low gas flow rates caused significant flux increase. The flux improvement was about  $\times 2.0$  for the minimum gas rate and only increased to  $\times 2.4$  for the maximum gas rate. Cabassud et al. [71] and Mercier et al. [72] studied the effect of slug flow on particle fouling in the ultrafiltration of bentonite suspensions with organic hollow fibers (0.01  $\mu\text{m}$ ,  $d_i = 0.93$  mm,  $L = 1.2$  m) and a mineral tubular membrane (0.02  $\mu\text{m}$ ,  $d_i = 15$  mm, 0.75 m). Although an initial flux decline also occurred for filtration with air injection, an enhancement of steady-state flux of 110% for hollow fibers and of 300% for tubular membranes was observed in the experiments. Gas sparging inside the tubes has also been shown to be efficient for improvement of performance of filtration of biomass. Mercier et al. [73] combined two-phase flow ultrafiltration (tubular: 50 kDa,  $d_i = 6$  mm,  $L = 1.2$  m) with a continuous alcohol fermentation process to investigate the feasibility of its long-term application in an MBR. Their results indicated that with air injection, a stable flux of 58  $\text{L}/\text{m}^2 \text{ h}$  was maintained over 100 h of fermentation until a final biomass concentration of 150 g (dry)/L was achieved, while the filtration without bubbling was prematurely stopped at about 30 h with a final concentration of 50 g (dry)/L due to membrane fouling. Performance enhancement for biomass filtration by gas injection was also reported by Imasaka et al. [74] for filtration of methane fermentation broth and by Vera et al. [75] for activated sludge.

Two-phase gas–liquid flow clearly reduces concentration polarization, and this can improve membrane separation. For example, Ghosh et al. [76] assessed the effect of gas sparging on protein fraction with BSA (MW 67,000) and lysozyme (MW 14,100) as model solutes. They reported that a nearly complete separation of these two model proteins was achieved with

**FIGURE 8.35** Bubbling enhanced flux for filtration of dextran solution. (Adapted from Cui, Z.F., Experimental investigation on enhancement of crossflow ultrafiltration with air sparging, in: Aterson, R.P. (Ed.), *Effective Membrane Processes-New Perspective*, Mechanical Engineering Publications, London, 1993, 237–245.)

two-phase flow ultrafiltration (MWCO 100 kDa), indicating an 18-fold increase in selectivity compared to that without air injection. The enhancement in selectivity was believed to be caused by the disruption of the concentration polarization so that solute retentions were closer to the intrinsic values. Although the depolarization decreased transmission for both BSA and lysozyme, the theoretical analysis suggested that air injection affected more the transmission of the more rejected component (BSA) so that high-separation efficiency was achieved.

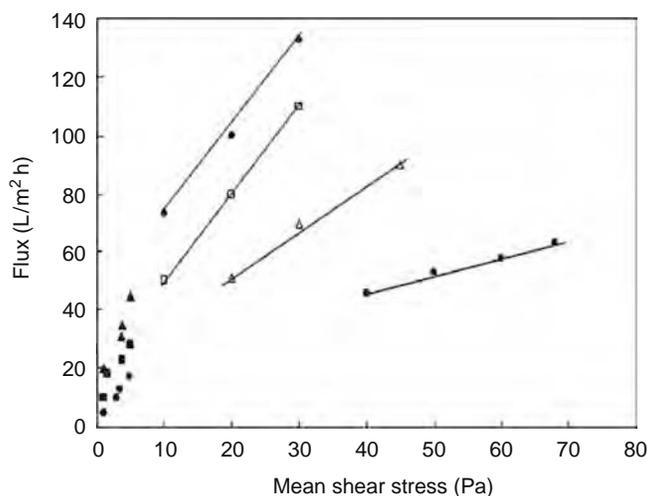

An assessment of the literature over a wide range of operating conditions and feeds indicates that flux enhancement for tubular membrane filtration can be affected by module configuration and operation conditions such as feed concentration, liquid velocity, bubble size, and TMP. The trends have been summarized by Cui et al. [77], as follows:

1. Benefit of bubbling becomes more significant when polarization is more severe, for example, at high TMP (or flux), a low liquid velocity, and a high feed concentration, due to the disruption effect of bubbling on concentration polarization.
2. Orientation of the tubular membrane is important. Cui et al. [78,79] indicated that greater flux enhancement can be obtained with vertical tubular membranes with rising bubbling coupled with a moderate downward liquid flow than with a horizontal tube. Cheng et al. [80,81] suggested that there is an optimal mounting angle for tubular membranes and they concluded that around 50° inclination gave the maximum enhancement because gas slugs on an angle move faster than in a vertical tube.
3. Flux enhancement by bubbling is significant in the laminar regime of liquid flow and becomes insignificant as the liquid flow Reynolds number approaches 2500–3000. The enhancement is relatively insensitive to the actual liquid flow over much of the laminar region. This is because the filtration is dominant by the secondary flows induced by the bubbles.

For bubbling-enhanced tubular membrane filtration, Cui et al. [77] have attributed the main mechanisms to

1. Bubble induced secondary flow: Moving bubbles generate secondary flows and wakes which promote local mixing near the membrane surface. Slug flow also results in an annular falling film as displaced liquid flows downward between the slug and the tube wall.
2. Physical displacement of the concentration polarization layer: Gas slugs can penetrate into the concentration polarization layer and displace the upper part of it.
3. Pressure pulsing caused by passing slugs: A moving slug causes pressure pulsing in the liquid around it, with a higher pressure at its nose and lower pressure at its tail. This is similar to imparting a local pulsatile flow during the filtration. In addition, injection of bubble may also result in an increase in mean TMP. Both of these factors could contribute to an increased flux.

Al-Akoum et al. [82] compared the bubbling, Dean flow, and vibrating-enhanced membrane processes in terms of the shear stress and the permeate fluxes obtained in filtration of yeast suspension. The filtration with two-phase flow was carried out using 15 mm ceramic mono tubular UF (permeability 250 L/m<sup>2</sup> h bar) and MF (permeability 1500 L/m<sup>2</sup> h bar) membranes with TMPs of 100 and 25 kPa for UF and MF, respectively. The yeast concentrations used in the two-phase experiments were 1

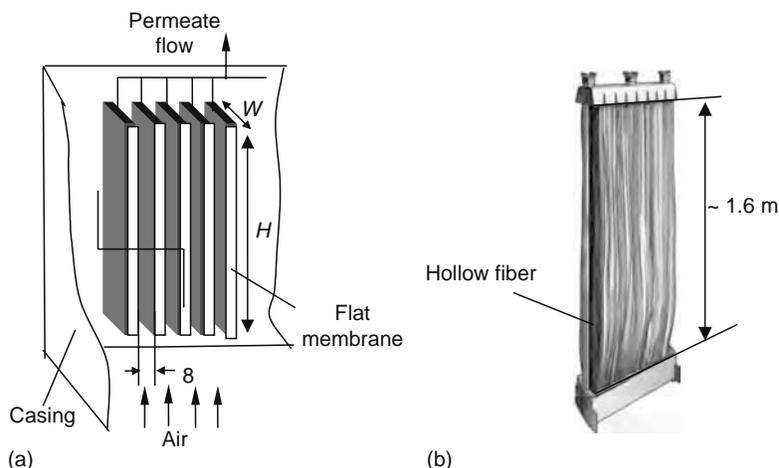

**FIGURE 8.36** Comparison of variation of permeate flux with mean wall shear stress two-phase flow, Dean, and vibratory shear-enhanced process (VSEP) system. (From Figure 6 in Al-Akroum, O., Mercier-Bonin, M., Ding, L., Fonade, C., Aptel, P., and Jaffrin, M.Y., *Desalination*, 147, 31, 2000. With permission.)

and 20 g/L and different ratios of gas flow rate to liquid flow rate were tested with a superficial liquid velocity of 0.45 and 0.38 m/s for UF and MF, respectively. The Dean flow experiments were conducted using yeast concentrations of 0.5–60 g/L with 0.93 mm (inside diameter) cellulose hollow fiber membranes (permeability 270 L/m<sup>2</sup> h bar) in helical form under a TMP of 110 kPa over a liquid velocity range of 0.81–1.64 m/s. A VSEP device was used for the vibrating-enhanced process and the yeast concentration used in the experiments was 20 g/L. Figure 8.36 shows the permeate flux and mean shear stress relationship for the three systems. The shear stress range for the three systems was determined as <10 Pa for two-phase flow, 10–40 Pa for the Dean flow system, and >40 Pa for the VSEP systems. For these shear ranges, it was observed that the flux with the three systems tested obeyed the empirical law:  $J = A\tau_{wm}^n$ , where  $\tau_{wm}$  is the averaged wall shear stress, with different coefficients shown in Figure 8.36. However, although the shear stress with the VSEP system was higher than those with the other two systems, a lower flux with VSEP was observed, indicating that other factors, such as membrane properties (materials, pore size, and surface morphology) and hydrodynamic instability behavior of the fluid, may affect membrane fouling and performance.

### 8.6.1.2 Bubbling with Submerged Membrane Systems

Bubbling seems to be an obvious strategy to induce flow and produce shear at the membrane surface in submerged systems to control concentration polarization and fouling. This is particularly attractive in MBRs for wastewater treatment where bubbling is already required as an oxygen supply. Figure 8.37a and 8.37b shows two different submerged membrane filtration modules:

**FIGURE 8.37** Submerged hollow fiber membrane module. (a) Flat sheet and (b) hollow fiber. (From Figures 19a and 21b in Cui, Z.F., Chang, S., and Fane, A.G., *J. Membr. Sci.*, 221, 1, 2003. With permission.)

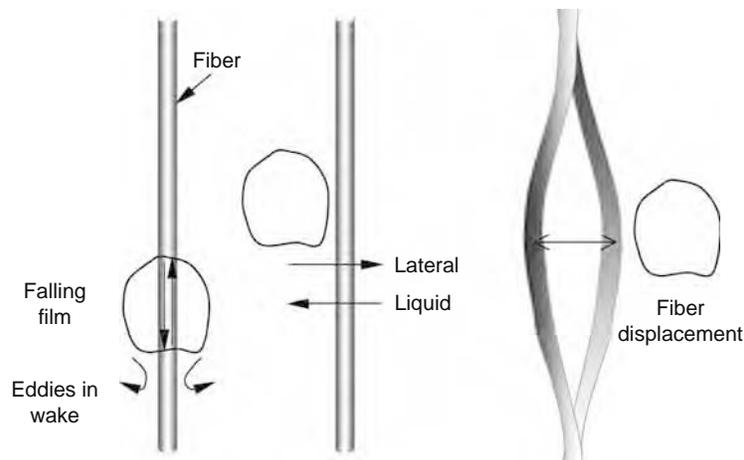

the submerged flat sheet system and the submerged hollow fiber membrane system. The flat sheet concept has been developed successfully by Kubota as a feature of their MBR system. As shown in Figure 8.37a, the Kubota flat sheet-submerged membrane unit may consist of multiple independent module panels that are arranged vertically at a distance of about 5–8 mm from each other. Each panel has its own support plate, membranes, and permeate collector. Air is injected from a distributor below the plates generating a well-defined flow in the channel. A potential advantage of the flat sheet arrangement is that the membranes are precisely located and more accessible to well-directed bubbles. The disadvantages are that membrane packing density is relatively low and vigorous backwashing is not feasible.

The submerged hollow fiber membrane was introduced in Japan in the mid-1980s. A patent by Tajima and Yamamoto [83] described a filter for nuclear power plants which incorporates U-shaped hollow fibers ( $0.1 \mu\text{m}$ ) in a vessel with intermittent air bubbling around the fibers to “vibrating the hollow fibers to remove solid particles trapped thereby.” Yamamoto et al. [84] are believed to be the first to report the use of submerged hollow fibers in a wastewater MBR; the role of the gas was described as for aeration, mixing, and inducing liquid flow. They also emphasized the importance of low-imposed flux and the use of intermittent suction for long-term stable operation of the submerged hollow fibers. This concept has become the generally accepted approach for submerged membranes in MBRs. In the early 1990s, Zenon developed their commercial submerged hollow fiber system with bubbling for wastewater and water treatment. Figure 8.37b shows the Zenon concept of the submerged hollow fiber membrane module, which involves use of a vertical loose fiber curtain supported at top and bottom and a gas bubble distribution system along the edge of the fiber bundle. Vigorous intermittent coarse bubble flow is applied to prevent particle deposition on the fiber surface.

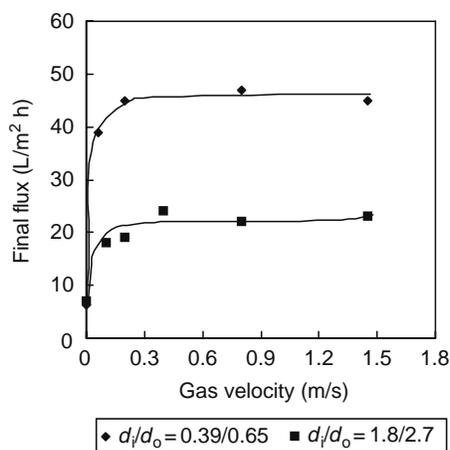

Figure 8.38 [77] depicts the likely mechanisms of depolarization and flux enhancement with vertical hollow fibers. For bubble flow outside hollow fibers, the vertical flow channels are less distinct and comprise the outer edge of fibers rather than randomly positioned. Surface shear on the hollow fiber membrane could be produced by large-scale liquid circulation induced by bubble flow. The local bubble behavior as bubbles or slugs move upward, including eddies in the wake and falling film around the slug, will enhance the mixing of the local liquid. In addition, the bubbles induce fluctuating liquid flow that transverses the fibers and causes lateral fiber movement, depending on the looseness of the fiber.

Figure 8.39 shows the results of tests at fixed TMP and plots ‘the steady-state flux’ versus gas flow rate using a test system with fibers vertically immersed in the stagnant feed with well-controlled spacing [85]. This study shows that bubbling could significantly enhance the performance of the filtration with a moderate gas rate but the enhancement did not increase much with further increase in the gas flow rate. The experimental results also indicate that the effect of bubbling on filtration could be affected by fiber size. From Figure 8.39 it can be seen that the final flux obtained in the filtration with the  $d_i/d_o = 0.39/0.65$  fiber was significantly higher than that with the  $d_i/d_o = 1.8/2.7$  mm fiber. Flux decline, defined as  $[100(\text{initial flux} - \text{final flux})/(\text{initial flux})]$ , is shown in Figure 8.40 for a wide range of fiber diameters; a clear advantage for the smaller diameter fiber is evident [85]. An explanation for the better response of the smaller fiber is that they are more flexible and able to move laterally as bubbles pass. This explanation is supported by the observation that the benefit of the small fiber increased with higher crossflow velocity or the injection of air. However, it should be noted that there is a practical constrain on using very small fiber diameters due to the increased pressure drop on the lumen side that causes a significant flux distribution along the fiber and adds to the energy cost.

The flexibility of the submerged hollow fibers under bubbling conditions can be promoted by having the fibers held loosely rather than tightly. Chang and Fane [86] indicated that there are significant differences in suction pressure profiles for filtration

**FIGURE 8.38** Mechanisms of cake depolarization—bubbles outside fibers. (From Figure 24 in Cui, Z.F., Chang, S., and Fane, A.G., *J. Membr. Sci.*, 221, 1, 2003. With permission.)

**FIGURE 8.39** Effect of gas velocity on final flux in filtration with submerged membranes. (From Figure 7 in Chang, S. and Fane, A.G., *J. Membr. Sci.*, 184, 221, 2001. With permission.)

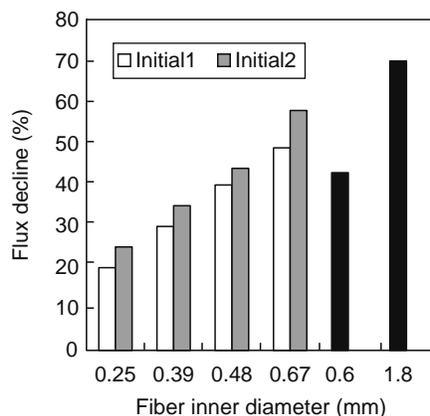

with tightly and loosely fixed fiber modules. Similarly, Wicaksana et al. [87] showed that the rate of suction pressure rise with a tight fiber was 50% faster than a fiber of 96% tightness, for a 5g/L yeast suspension and the same airflow rate. In addition, the depolarization due to fiber movement was shown to be up to 40% of the overall bubbling effect. Commercial hollow fiber systems have recognized the importance of a certain degree of fiber looseness and flexibility.

### 8.6.2 SOLID-LIQUID TWO-PHASE FLOW—BY PARTICLE ADDITION

An early study by Bixler and Rappe [88] showed that glass beads (up to 100  $\mu\text{m}$  size) added to a stirred cell UF of a macrosolute were able to significantly enhance flux. The mechanism was probably eddy formation and thinning of the concentration boundary layer by particle interaction. Similar effects were reported by Fane [89] who noted that enhancement required significantly supramicron particles and that smaller particles could in fact add to the deposit resistance.

The added-particle effect is also evident in the application of fluidized beds to provide turbulence promotion. Figure 8.41 is a schematic diagram of a combined tubular membrane-fluidized beds system. It consists of a tubular membrane module, fluidized particles, a feed pump, and the feed storage tank. During the operation, the particles are fluidized by the pumped liquid flow. The drag forces on the solid particles are a function of the liquid velocity and the porosity of the bed. Usually the liquid velocity will be adjusted to a value that results in a balance between the gravity and drag forces so that the particle will not be hydraulically transported. The enhanced mass transfer is caused by the irregular flow of the liquid between the particles and the erosive action of the randomly moving particles at the membrane surface.

Noordman et al. [90] assessed the performance enhancement of ultrafiltration of 10 g/L BSA solution by fluidized particles of different materials and size using a polysulfone tubular membrane with inside diameter of 14.4 mm and 1.75 m length and an MWCO of 10 kDa. Table 8.4 summarizes the fluxes and the mass transfer coefficients obtained under different experimental

**FIGURE 8.40** Effect of fiber diameter on flux decline in filtration with submerged hollow fiber. (From Figure 8 in Chang, S. and Fane, A.G., *J. Membr. Sci.*, 184, 221, 2001. With permission.)

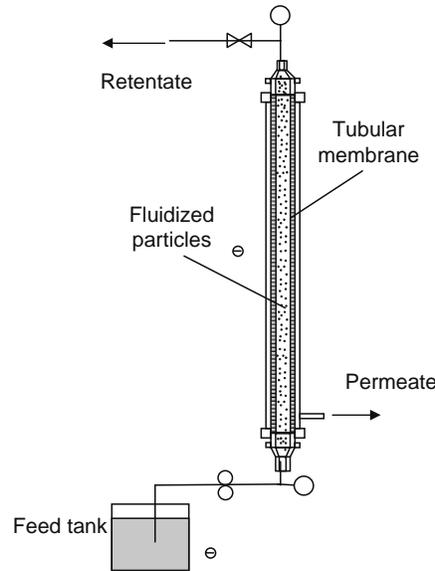

FIGURE 8.41 Schematics of tubular membrane with fluidized particles.

conditions. The mass transfer coefficients have been calculated using the film model based on the experimentally determined fluxes with the assumption of a constant gel concentration of 120 g/L. From Table 8.4 it can be seen the fluidized particles resulted in an enhancement in mass transfer of up to 15. The particle size and density seem to only have a limited effect on the process. Given that increasing the particle size and density may increase the risk of membrane damage by the fluidized particles [91] and require greater energy consumption, Noordman et al. [90] suggested that light and relatively small particle should be used in fluidized particle-enhanced membrane processes.

## 8.7 OTHER TECHNIQUES

### 8.7.1 ELECTROFILTRATION

Electrofiltration is related to application of an electric field to improve the efficiency of pressure-driven membrane filtration [92]. Figure 8.42 shows the basic configuration of electrofiltration, where an electric field is applied across micro or ultrafiltration membranes in flat sheet, tubular, and SWMs. The electrode is installed on either side of the membrane with the cathode on the permeate side and the anode on the feed side. Usually, the membrane support is made of stainless steel or the membrane itself is made of conductive materials to form the cathode. Titanium coated with a thin layer of a noble metal such as platinum could, according to Bowen [93], be one of the best anode materials. Wakeman and Tarleton [94] analyzed the particle trajectory in a combined fluid flow and electric field and suggested that a tubular configuration should be more effective in use of electric power than flat and multitubular module.

**TABLE 8.4**  
Mass Transfer and Flux for Filtration with Different Fluidized Particles

Material	$d_p$ (mm)	$\rho_s$ (kg/m <sup>3</sup> )	$k$ ( $\mu\text{m/s}$ )	Flux (L/m <sup>2</sup> hr)	Flux Enhancement
Empty tube	—	—	0.54	6.26	1
Glass	1	2900	4.3	49.8	8.0
Glass	1	2900	6.4	74.2	11.8
Glass	0.46	2900	5.9	68.4	10.9
Stainless steel	1	7800	7.6	88.1	14.07
Stainless steel	2	7800	8.1	93.9	15

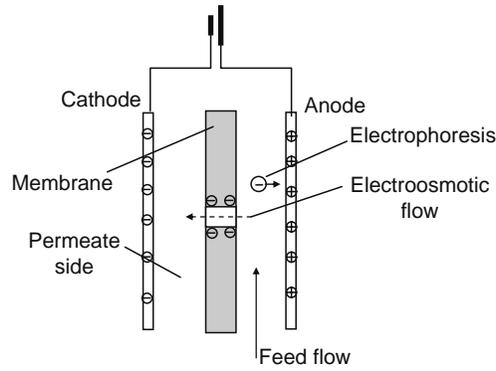

FIGURE 8.42 Schematics of electrofiltration.

Filtration enhancement by an electric field results from the influence of the applied electric field on particle deposition via electrophoresis. Most particles acquire a surface charge when in contact with a polar (e.g., aqueous) medium due to ionization, ion adsorption, and ion dissolution. This surface charge influences the distribution of nearby ions of opposite charge and leads to the formation of an electrical double layer at the interface between the particle and the dispersion medium (water). An imaginary boundary, the surface of shear, separates the double layer into two parts: the bound and mobile parts. If a voltage gradient is applied the charged particle (plus bound ions) tends to move in the appropriate direction, whilst the ions in the mobile part of the double layer show a net migration in the opposite direction carrying solvent along with them. Electrophoresis is the movement of the charged particle relative to stationary liquid under the effect of an applied electric field. This movement depends on the potential at the surface of shear, known as the zeta potential, and the strength of the electric field applied. The electrophoretic mobility ( $u_E$ ), or the electrophoretic velocity ( $v_E$ ) produced by unit electric field strength ( $\mathbf{E}$ ), can be related to the zeta potential by

$$u_E = \frac{v_E}{\mathbf{E}} = \frac{\varepsilon_r \xi}{\eta} \quad (8.34)$$

where

$\varepsilon_r$  is the electrolyte permittivity

$\xi$  is the zeta potential

$\eta$  is the viscosity

Surfaces in contact with the aqueous media are more usually negatively charged (negative zeta potential in a liquid) than positively charged; the effect is pH dependent with negative charge increasing with pH. When an external electric field is applied across the membrane with its anode in the feed side, the electrophoretic movement of negatively charged particles in the feed be away from the membrane and will augment diffusive back transport.

This means that the conventional film model relationship can be modified to show the augmentation due to electrophoretic velocity ( $v_E$ ) [92], so

$$J = \ln\left(\frac{C_w}{C_b}\right) + v_E \quad (8.35)$$

The critical electric field strength at which the net migration of the particles toward the membrane is zero can be calculated by combining Equations 8.34 and 8.35 with  $C_w = C_b$ .

$$\mathbf{E}_{\text{crit}} = \frac{J\eta}{\varepsilon\xi} \quad (8.36)$$

When the electric strength is equal to or larger than the critical value the particle deposition can be arrested by the electrophoretic movement or the particles will even move in the opposite direction to the permeate flow. It should be noted that electrofiltration requires charged particles in the feed, and that the zeta potential will depend on the pH and the ionic environment. This means it will not be effective close to the isoelectric point or with raised levels of salts.

Another electrokinetic phenomenon that may occur during electrofiltration is electroosmosis or the movement of liquid relative to a stationary charged surface. If the membrane itself is charged, the electrical field applied across the membrane will

try to shear off the mobile part of the double layer of the pore wall, leading to an electroosmotic flow in the pores. For a negatively charged membrane, the electroosmosis flow will be in the same direction as the permeate flow if the applied electric field is as shown in Figure 8.42. It has been reported the electroosmosis could result in up to 15% enhancement in permeate flux [95], although the main process enhancement mechanism has been attributed to the electrophoretic movement of the charged particles that limit cake formation. Visvanathan and Ben Aim [96] describe the combined application of electrofiltration and electroosmotic backwashing, which involves polarity reversal to keep both the membrane and the electrode free from deposits.

Apart from electrokinetic phenomena, the electrofiltration process may also be affected by the electrochemical reactions that occur at the electrodes. A typical cathodic process and anodic process in aqueous systems are the formation of hydrogen gas at the cathode and oxygen at the anode:

Electrochemical reactions can be harmful to the filtration processes by causing foaming or pore obstruction due to production of gas. However, anodic oxidation can also be used as a method of removing organic molecules from the effluent. It seems further studies are still needed to justify the role of electrode reactions in electrofiltration.

The flux enhancement by electric field has been reported by many researchers. Huotari et al. [97] reported five time increase in flux by applying 2.4 kV/m external electric field in filtration of oily waste water using a tubular carbon fiber—carbon composite membrane with membrane pore size of 0.05  $\mu\text{m}$  and an inside diameter of 5.7 mm with the membrane itself as the cathode and a stainless steel of 2 mm in diameter located in the central of the tubular membrane as the anode. For this enhancement, the zeta potential of the particle and the membrane was  $-67$  and  $-50$  mV, respectively. Akay and Wakeman [98] obtained 10-fold enhancement of the flux using an electric field strength in the microfiltration of an anionic, hydrophobically modified water-soluble polymer (HMWSP). Rios et al. [99] reported that the flux in filtration of gelatin solution can be increased from 4 to 12  $\text{L}/\text{m}^2 \text{h}$  with an electric field strength of 2.4 kV/m. To achieve this effect, it was necessary to operate at a pH above the isoelectric point of gelatin to give it a net negative charge.

Although it has been reported that an external DC electric field can induce an electrophoretic back transport that can significantly enhance flux in crossflow membrane filtration, its commercial implementation appears to be restricted by several factors. These include lack of suitably inexpensive corrosion-resistant electrode materials, concerns about energy consumption, and the complexity of module manufacture.

The application of an external AC field effect has also been reported to enhance the performance of RO membranes [100]. The electromagnetic field is said to reduce fouling by scale formers and to reduce particulate fouling and biofilm development. The mechanisms involved are still under investigation but could include a change to crystal morphology and aggregation of particles and bacteria, raising their critical flux.

### 8.7.2 ULTRASOUND-ENHANCED FILTRATION

Ultrasound occurs at a frequency above 16 kHz and is typically associated with the frequency range of 20 kHz to 500 MHz. The frequency level is inversely proportional to the power output. The high intensity, low frequency ultrasound can alter the state of the medium chemically or physically and be used for applications such as cleaning, emulsification, crystallization, sonochemistry, etc. [101]. The chemical and physical effects of ultrasound are related to the cavitation phenomenon induced by rarefaction and compression of the sound wave. When ultrasound is irradiated through a liquid medium, an alternating adiabatic compression and rarefaction cycle of the medium occurs. During the rarefaction period, negative pressures occur and microbubbles can be formed and grown at sites where there is some gaseous impurity. The formed bubbles may suddenly collapse during the compression period after a few acoustic cycles with a release of energy. This helps to generate micromixing in the liquid, or form liquid microjets near a solid surface, or cause chemical changes in reactants in the cavitation bubbles. The power dissipated ( $P_{\text{diss}}$ ) in the liquid medium can be determined calorimetrically in terms of the change in temperature of the medium with the assumption that all the energy delivered to the system is dissipated as heat, as shown by

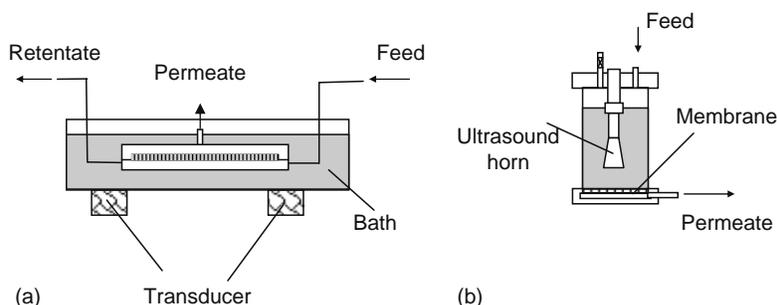

$$P_{\text{diss}} = \left( \frac{\Delta T}{\Delta t} \right) C_p M \quad (8.39)$$

where

$\Delta T$  is the change of temperature during time period  $\Delta t$

$C_p$  is heat capacity of water

$M$  is the water mass

**FIGURE 8.43** Schematics of ultrasound membrane filtration systems. (a) Ultrasound bath and (b) ultrasound horn.

Figure 8.43 depicts two typical configurations used to assess the effect of ultrasound on membrane filtration and cleaning. Figure 8.43a shows a bath configuration where the crossflow cell is immersed in a water bath with ultrasonic transducers attached to the bottom of the bath. Figure 8.43b shows horn configuration where an ultrasonic horn is installed in a conventional cell.

Juang and Lin [102] assessed the effect of ultrasound on flux recovery in the ultrafiltration (YM 10, regenerated cellulose) of  $\text{Cu}^{2+}$ -polyethylenimine (PEI) solution and W/O/W solutions using a filtration cell equipped with an ultrasound horn (Misonix Sonicator 3000 [600 W, 20 kHz], horn type 200). Their results indicated that the ultrasound can even increase the pure water flux due to the cavitation induced TMP increase. For ultrafiltration of  $\text{Cu}^{2+}$ -PEI solution at 69 kPa, a 70%–80% flux recovery was obtained for an ultrasonic power  $>30$  W at the optimal tip height 65 mm. For ultrafiltration of the W/O/W emulsions, a 30%–60% flux recovery was achieved at 145 W, depending on the volume ratio of the water to oil in the emulsions. Analysis, based on the resistances in series model, revealed that the resistances caused by pore blocking and cake compressibility were reduced by increased ultrasound power. They also reported that the structure of the regenerated cellulose and polyethersulfone membranes tested could be affected by ultrasonics at powers greater than 80 W but no obvious change was observed with the polyvinylidene fluoride and polyacrylonitrile membranes. Simon et al. [103] defined an imaginary ultrasonic stirring speed at which the mass transfer coefficient will be similar to that obtained by a traditional stirrer at the same stirring speed. They suggested that the ultrasonic stirring speed is proportional to the ultrasound power by comparing the mass transfer coefficients obtained in ultrafiltration of dextran (500 kDa) using a classical stirred cell and an ultrasound-assisted cell. Kobayashi et al. [104] assessed the effect of ultrasonic frequency on ultrasound membrane cleaning for dextran-fouled ultrafiltration membranes (10 kDa) and milk-fouled cellulose microfiltration membranes using a crossflow cell immersed in an ultrasound bath. For the tested frequencies of 28, 45, and 100 kHz, they reported the cleaning can be significantly affected by the frequency with 28 kHz identified as the optimal. Muthukumaran et al. [105] examined the effect of low power ultrasonics on the UF of dairy whey. They found flux enhancements of  $\times 1.2$ – $\times 1.7$  and that this could be improved when used in combination with flow channel spacers.

All the reported studies indicate that low frequency ultrasound can enhance the filtration process and improve membrane cleaning efficiency to some extent. However, reducing energy losses, increasing the efficiency of the ultrasound and system scale-up are challenges that need to be overcome before serious commercial application can be considered.

## 8.8 CONCLUSIONS

Many strategies are available for the enhancement of performance of membrane processes. All of these techniques aim to limit the effect of concentration polarization at the membrane surface. The majority of techniques is hydrodynamic and therefore involves additional energy input or some extra design feature. To obtain the enhancement in performance, there is an investment that requires a pay back. Thus in each case, there will be a trade-off between operating and capital cost that provides an optimum condition that minimizes total production cost. The most prevalent strategies for enhancement are the flow channel spacers used in the SWM for RO, NF and some UF, and two-phase flow by air sparging used in the increasingly ubiquitous-submerged membranes applied to water and wastewater treatment. High shear devices, with rotations and vibrations, also demonstrate significant ability for enhanced performance, particularly for difficult feed materials in niche applications.

## NOMENCLATURE

$B$	pitch of helical coil tube
$C$	coefficient (Equation 8.1)
CFD	computational fluid dynamics
$d_b$	bubble diameter

$d_f$	filament diameter of spacer
$d_i$	inner diameter
$d_o$	outer diameter
$d_p$	particle diameter
$d_{\text{pore}}$	membrane pore diameter
$d_{\text{ti}}$	tube internal diameter
$d_v$	displacement
$De$	Dean number
$D_t$	coil diameter
$D_t'$	modified coil diameter
$D$	dialysis
DOTM	direct observation through membrane
$E_t$	energy consumed per unit volume of filtrate
ED	electrodialysis
$F$	frequency
$f_c$	friction factor in a coil tube
$f_s$	friction factor in a straight tube
$J_{\text{cr}}$	critical flux
$J_d$	design flux
$l_m$	length of filament of spacer
$L$	length
$L_f$	filter length
$L_s$	length of space channel
$m$	coefficient
MBR	membrane bioreactor
MF	microfiltration
MWCO	molecular weight cut off
$n$	coefficient
NF	nanofiltration
$p$	coefficient
$P$	pressure
$P_d$	overall power expenditure
$\Delta P_L$	pressure drop along the filter
$\Delta P_{\text{tm}}$	transmembrane pressure
PV	pervaporation
$Q$	coefficient
$Q_f$	feed flow rate
$Q_p$	permeate flow rate
$R$	radial coordinate
$r_p$	particle radius
$R$	radius
$Re$	Reynolds number
RO	reverse osmosis
$s$	coefficient
$Sc$	Schmidt number
$Sh$	Sherwood number
$S_{\text{sp}}$	filament surface area of spacer
$S_{\text{vsp}}$	specific surface area of spacer
SWM	spiral wound module
$U_b$	bubble rising velocity
$V_m$	mean azimuthal velocity
$T$	time
TMP	transmembrane pressure
UF	ultrafiltration
$u_E$	electrophoretic mobility
$v_E$	electrophoretic velocity
$V_{\text{sp}}$	filament volume of space filament

$V$	velocity
$V_{\text{total}}$	channel volume of spaced-filled channel
$w$	axial velocity of pulsatile flow
$z$	coordinate

### GREEK LETTERS

$\varepsilon$	voidage of spacer
$\varepsilon_r$	electrolyte permittivity
$\phi_b$	solid volume fraction in the solution

## 9.1 INTRODUCTION AND BACKGROUND

Separation of hydrocarbons and their removal from various gaseous and liquid mixtures are important objectives of chemical and petrochemical industries. These objectives can be achieved by adsorption, rectification, or cryogenic technology. In the last 20 years this list of traditional methods was supplemented by membrane technology. A significant corpus of patent and literary data accumulated so far requires generalization (about 2000 documents over the last 20 years). The flow of patent and periodic information on the problem of membrane separation of hydrocarbons is steadily growing [1–4]. The flow is dominated by articles in journals whereas the share of patents is only about one third. This indicates that at present researchers are mainly taking a scientific, rather than commercial, interest in the problem [1].

Several areas can be singled out in membrane separation techniques differing by a number of criteria, primarily by the material of construction of the membrane's selective layer. Materials of construction of the membrane's selective layer can be broken down into the following groups: polymers (41% in the total information flow), inorganic materials (37.7%), liquids (4.8%), combined organic/inorganic materials (3.2%), and other materials (13.1%). A noteworthy fact is the growing interest shown by researchers in inorganic membranes [1]. A major breakthrough in the development of inorganic membranes (zeolites, aluminium oxide, ceramics, silica, various metals, metal oxides, etc.) has been on the cards for the last 10 years. However, the use of membranes with inorganic selective layers is now only at the stage of intense investigation and is still a long way from commercial implementation. The share of patents in the information flow on this subject is only 19.9% [1].

Membranes having a polymer-based selective layer make up the most broadly represented segment in the information flow. In terms of the share in this total information flow, polymer materials can be arranged in the following series: polyimides (15.3%), polyolefins (8.2%), polysulfones (7.2%), polyamides (7.2%), fluorine-containing polymers (4.8%), and organosilicon polymers (7.1%). Polyamides are the most widely represented class of polymers in both periodical and patent literature. As years go by, the interest shown by researchers (especially in Japan) in the use of polyimides is not waning. A lot of documents can also be found in the information flow that makes reference to the use of rubbery polymer materials, including polysiloxanes, which in fact indicates that practical use of these materials may hold much promise [1].

The materials of the selective layer of the membranes dominating in the data are polymers. The polymers used can be both glassy and rubbery. It is therefore worthwhile to consider physicochemical regularities of hydrocarbon mass transfer across polymer membranes.

## 9.2 GENERAL CONSIDERATIONS: PHYSICO-CHEMICAL REGULARITIES OF HYDROCARBON PERMEATION IN MEMBRANES BASED ON GLASSY AND RUBBERY POLYMERS

There is no fundamental qualitative difference in mechanisms of low molecular weight (MW) penetrant diffusion in polymers above and below glass transition temperature,  $T_g$ , of the polymers [5,6]. The difference lies only in the fact that the movement of structural units of the macromolecule that are responsible for the transfer of penetrant molecules takes place at different supermolecular levels of the polymer matrix. At  $T > T_g$  the process of diffusion takes place in a medium with equilibrium or near-equilibrium packing of chains, and the fractional free volume,  $\nu_f$ , in the polymer is equal to the fractional free volume in the polymer determined by thermal mobility of structural units of macromolecules  $\nu_{f(T)}$ , i.e.,  $\nu_f = \nu_{f(T)}$ . At  $T < T_g$  the process of diffusion comes about under nonequilibrium packing conditions, although there exists a quasi-equilibrium structural organization of the matrix, where  $\nu_f > \nu_{f(T)}$ . It is assumed that in this case  $\nu_f = \nu_{f(T)} + \nu_{f(v)}$ , where  $\nu_{f(v)}$  is the fractional free volume responsible for nonequilibrium character of the polymer matrix [5].

Permeability of low MW penetrants in polymers is determined by both thermodynamic (sorptive) and kinetic (diffusive) factors.

### 9.2.1 THERMODYNAMIC FACTOR OF PERMEABILITY

In the absence of specific penetrant/polymer interactions, solubility of the penetrant is determined mainly by its chemical nature and depends on condensability, which is represented by boiling temperature ( $T_b$ ), critical temperature ( $T_{cr}$ ), or Lennard–Jones constant ( $\epsilon/k$ ) [7,8]. It is known that in the hydrocarbon series the increase in condensability is accompanied by a parallel increase in the size of molecules (Table 9.1 [9–17]). It is therefore not surprising that in both glassy and rubbery polymers correlations of hydrocarbon solubility in the polymers with condensability and sizes of hydrocarbon molecules are observed (Figures 9.1 through 9.3).

To analyze sorption of penetrants, including hydrocarbons, in glassy polymers, the dual-mode sorption model is most frequently used. For a number of glassy polymers, correlations between the constants of the dual-mode sorption model and the condensability of hydrocarbons have been established (see, e.g., Figure 9.4a through 9.4c and data presented in Refs. [18–20]). Temperature dependence of model constants is described by Vant-Hoff equation, where the exponent contains heat of penetrant sorption  $\Delta H_s$ . This quantity is essentially dependent on the heat of penetrant condensation,  $\Delta H_{\text{cond}}$ :  $\Delta H_s = \Delta H_{\text{cond}} + \Delta H_1$ , where  $\Delta H_1$  is partial molar enthalpy of penetrant dissolution in the polymer,  $\Delta H_1 = [\partial(\Delta G_1/T)/\partial(1/T)]_c$ ,  $\Delta G_1$  is the partial molar free

**TABLE 9.1**

energy of the penetrant dissolution in the polymer. The sorption of easily condensable hydrocarbons features negative values of sorption heat as a result of high negative values of their condensation heat.

A linear correlation between solubility of various gases in glassy polymers and distance between chains of macromolecules has been established using x-ray structural analysis. The solubility of gases, including lower hydrocarbons, increases with this distance [8,21,22]. Similarly it has been found that the solubility of gases in glassy polymers increases with the molar fraction of free volume of the polymer (see Figure 9.5) [8,23,24]. It was reported that the Langmuir mode saturation constant is

dependent on the accessible free volume of the polymer, and the accessible free volume of the same polymer decreases with the increase in the size of the penetrant molecule [18].

The solubility of hydrocarbons in rubbery polymers can be described in more detail by several theories of solutions using various criteria of thermodynamic affinity [7,25–28], of which the Flory–Huggins theory is the most popular one. It takes into account the volume content of the penetrant dissolved in the polymer and the change in the length of the polymer's thermodynamic segment as a result of dissolution [7]. However, it should be pointed out that to describe dissolution, a refined dual-mode sorption model can be used, e.g., the model by Pace and Datyner [7,29,30].

## 9.2.2 KINETIC FACTOR OF PERMEABILITY

Diffusion selectivity is based on the ability of the polymer matrix to transmit molecules of a certain shape and size. This ability is determined by the structure of the polymer and the rigidity of the macromolecular ensemble as well as by the properties of the penetrant, the size and shape of its molecules.

### 9.2.2.1 Effective Sizes of Diffusing Molecules

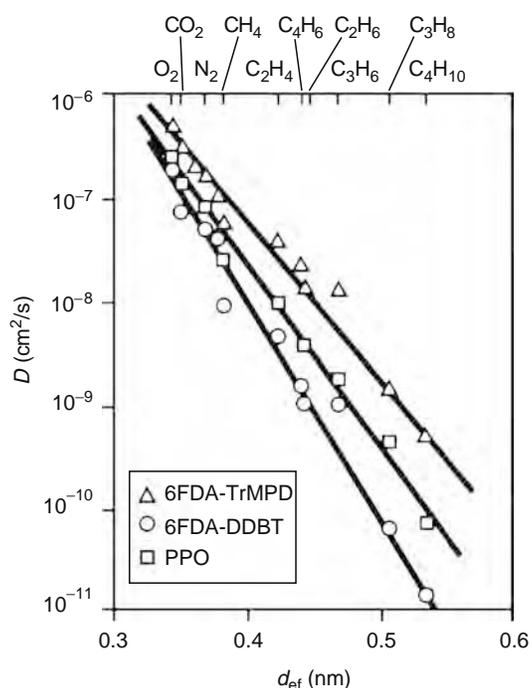

To estimate the molecular size of low MW penetrants permeating through the polymer membrane, the following parameters are used: Van der Waals volume of the molecule,  $V$ ; collision diameter calculated from Lennard-Johns potential,  $\sigma_{LJ}$ ; kinetic diameter of the molecule  $\sigma_{kt}$  determined using molecular sieves; minimum cross-section of the molecule  $a_D$ , determined from Stuart's molecular model [9–16]. Values of these parameters can differ significantly, especially for molecules of oblong shapes (Table 9.1). Comparison of molecules of inorganic gases and methane in terms of collision diameter  $\sigma_{LJ}$  and kinetic diameter  $\sigma_{kt}$  shows that the difference between the two is insignificant and both can be used to estimate the size of diffusing molecules. An exception is the quadrupole molecule of  $\text{CO}_2$ , whose effective diameter is determined on the basis of the correlation between  $\ln D$  and the diameters of molecules of several penetrants in various polymers [8]. The difference between  $\sigma_{LJ}$  and  $\sigma_{kt}$  increases with the increase in the number of carbon atoms in the hydrocarbon molecule.

The effect of the size of hydrocarbon molecules on their diffusion coefficients in glassy and rubbery polymers has been discussed in the literature [17,31–33]. It has been shown that effective cross-sections of diffusing hydrocarbon molecules determined from diffusion of permanent gases, whose molecular cross-section was derived from Stuart's model, have different

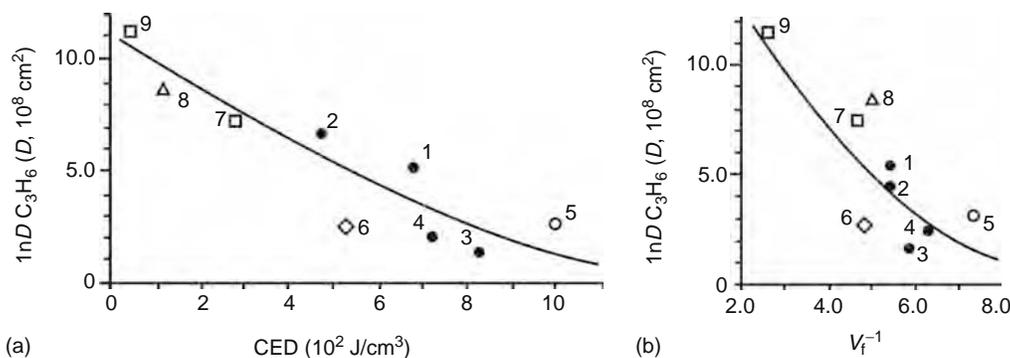

**FIGURE 9.7** Dependence of hydrocarbon diffusion coefficients on the effective diameter of hydrocarbon molecules  $d_{ef}$  at temperature,  $T = 323$  K and pressure of 2 atm (1 atm for  $C_4H_6$  and  $C_4H_{10}$ ) in various glassy polymers: 6FDA-TrMPD and 6FDA-DDBT are polyimides, PPO is polyphenylene oxide (values of effective diameter of molecules were: 0.35 nm for  $CO_2$ , 0.44 nm for  $C_4H_{10}$ , and for other gases  $d_{ef} = \sigma_{LJ}$  was assumed). (From Okamoto, K., Noborio, K., Hao, J., Tanaka, K., and Kita, H., *J. Membr. Sci.*, 134, 171, 1997. With permission.)

its oblong shape. The effective diameter of the  $C_4H_6$  molecule that reflects the diffusion of this vapor was 0.4 nm. This value was obtained using linear correlation between  $\ln D$  and effective diameters of molecules known for other gases and vapors.

### 9.2.2.2 Effect of Cohesion Energy Density of the Polymer on Diffusion of Hydrocarbons in the Polymer

In accordance with the equation for the activation energy of diffusion proposed by Meares [31], cohesion energy density (CED) of the polymer has a significant effect on diffusion coefficients of lower hydrocarbons. This is especially typical of rubbery polymers: an increase in CED results in reduction of diffusion coefficients. Similar dependencies also apply to glassy polymers [9,32]. For example, Figure 9.8a shows the dependence of diffusion coefficient of propylene on CED of both glassy and rubbery polymers.

**FIGURE 9.8** Dependence of propylene diffusion coefficients in various polymers on cohesion energy density (CED) of the polymer (a) and on inverse mole fraction of free volume of the polymer (b): ●1, 6FDA-TeMPD polyimide; ●2, 6FDA-TrMPD polyimide; ●3, 6FDA-DDBT polyimide; ●4, 6FDA-ODA polyimide; ○5, BPDA-TeMPD polyimide; ◇6, PPO, polyphenylene oxide; □7, P4MP, polymethylpenetene; △8, 1,2PB, polybutanediene; □9, PDMS, polydimethylsiloxane. Membr. Sci.*, 134, 171, 1997.)

### 9.2.2.3 Effect of Free Volume of the Polymer on Diffusion of Hydrocarbons in the Polymer

The effect is especially significant in the case of glassy polymers [8,9,32]. It was shown in several studies that diffusion coefficients of penetrants, including hydrocarbons, decrease with the decrease in molar fraction of free volume of the polymer (see, e.g., Figure 9.8b).

### 9.2.2.4 Concentration Dependencies of Diffusion Coefficients of Hydrocarbons

The models most frequently used to describe the concentration dependence of diffusion and permeability coefficients of gases and vapors, including hydrocarbons, are: transport model of dual-mode sorption (which is usually used to describe diffusion and permeation in polymer glasses) as well as its various modifications; molecular models analyzing the relation of diffusion coefficients to the movement of penetrant molecules and the effect of intermolecular forces on these processes; and free volume models describing the relation of diffusion coefficients and fractional free volume of the system. Molecular models and free volume models are commonly used to describe diffusion in rubbery polymers. However, some versions of these models that fall into both classification groups have been used for both rubbery and glassy polymers. These are the models by Pace–Datyner and Duda–Vrentas [7,29,30].

The experimental and theoretical data presented in the literature show that selective permeability of rubbery polymers for hydrocarbons follows the general rule of being dominated by the sorption component. Selective permeability of glassy polymers for hydrocarbons follows the general rule of being dominated by the diffusion component.

Thus, the permeation of hydrocarbons in polymer membranes is governed by the basic regularities typical of permeation of low MW penetrants, modified however by certain peculiarities related to the structure and shape of hydrocarbon molecules. We will now discuss the physicochemical regularities of hydrocarbon separation and removal using polymer membranes, by trying to reveal the relationship between the chemical structure of polymers and their separation properties with respect to mixtures containing hydrocarbons. It follows from literary data that rubbery polymers are mainly used in gas/vapor separation processes for selective separation of hydrocarbon vapors from their mixtures with air as well as in pervaporation processes for the removal of hydrocarbons from their aqueous solutions. In practice, glassy polymers are used for separation of olefins and paraffins as well as for separation of aromatic, alicyclic, and aliphatic hydrocarbons.

## 9.3 SEPARATION AND REMOVAL OF HYDROCARBONS USING MEMBRANES BASED ON RUBBERY POLYMERS

### 9.3.1 SELECTIVE SEPARATION AND REMOVAL OF HYDROCARBON VAPORS FROM GAS MIXTURES

The polymer materials mainly used for the selective separation of hydrocarbon vapors from their mixtures with air are organosilicon polymers.

#### 9.3.1.1 Effect of Chemical Composition of Organosilicon Polymers on Their Gas Separation Properties to Hydrocarbons

This subject was dealt with by several researchers, most comprehensively by Stern [19,20,34–37]. Permeability of several gases and vapors, including hydrocarbons, in various organosilicon polymers has been investigated after modification of chemical composition of the polymers by introducing substituent groups in both side and main chains. The following polymers have been investigated:  $[-(\text{CH}_3)(\text{R}_1)\text{Si}-\text{O}-]_n$ , where  $\text{R}_1 = -\text{CH}_3$ ;  $-\text{C}_2\text{H}_5$ ;  $-\text{C}_3\text{H}_7$ ;  $-\text{C}_8\text{H}_{17}$ ;  $-\text{CH}_2\text{CH}_2\text{CF}_3$ ;  $-\text{C}_6\text{H}_5$ ; and  $[-(\text{CH}_3)_2\text{Si}-\text{R}_2-\text{Si}(\text{CH}_3)_2-\text{O}-]_n$ , where  $\text{R}_2 = -(\text{CH}_2)_2-$ ;  $-(\text{CH}_2)_6-$ ;  $-(\text{CH}_2)_8-$ ;  $-m\text{C}_6\text{H}_4-$ ;  $-p\text{C}_6\text{H}_4-$ . Results of the research are presented in Tables 9.2 and 9.3, and Figure 9.9.

It follows from analysis of these results that the increase in the volume of the substituent group results in higher rigidity and density of the polymer. This manifests itself in higher glass transition temperatures and densities of the polymers. Introduction of substituent groups into the side chain has a significantly greater effect on these parameters as compared to substitutions in the main chain. Variation in flexibility of the polymer chain also has a significant effect on permeability. In this connection it makes sense to compare polymers  $[-(\text{CH}_3)_2\text{Si}-\text{CH}_2-]_n$  and  $[-(\text{CH}_3)_2\text{Si}-(\text{CH}_2)_8-\text{Si}(\text{CH}_3)_2-\text{O}-]_n$ . The relatively low permeability of the first polymer is due to the lack of flexible siloxane  $-\text{Si}-\text{O}-$  bonds in the main chain. The presence of only one siloxane bond per eight recurrent  $-\text{CH}_2-$  groups in the second polymer makes the chains much more flexible and results in a more than twofold increase in permeability as compared with the first polymer (see Table 9.2).

The permeability of polymers decreases with the increase in their glass transition temperature. This dependence becomes more pronounced with increasing kinetic diameter of penetrant molecules (Figure 9.9).

It can be seen from the data presented in Table 9.2 that the parallelism of the decrease in permeability with the increase in glass transition temperature of the polymer is somewhat disrupted for He and  $\text{CO}_2$ . Helium has the lowest solubility among the penetrants under study. However, the permeability of organosilicon polymers for helium is higher than could be expected from

Notes:  $T = 308$  K; pressure,  $p = 0$  Pa.

its solubility. Thus, polymers with  $R_1 = -CH_3$ ;  $-C_2H_5$ ;  $-C_3H_7$ ;  $-C_8H_{17}$ ;  $R_2 = -(CH_2)_{2-8}-$ ;  $-m,p$  C<sub>6</sub>H<sub>4</sub>— are more permeable for helium than for nitrogen, although the solubility of nitrogen in them is considerably higher than that of helium. A similar regularity exists for polymers with  $R_1 = -CH_2-CH_2-CF_3$ ;  $-C_6H_5$ ;  $R_2 = -mC_6H_4-$ ;  $-pC_6H_4-$ . Introduction of bulky substituent groups into the side or main chain of the polymer changes the diffusion of all penetrants; however, the diffusion of helium decreases to a smaller degree than that of other penetrants. These regularities are probably due to fast diffusion of helium in polymers, as a result of the small kinetic diameter of its molecules compared to those of other gases and vapors. A number of polymers, e.g., polymers with  $R_1 = -CH_2-CH_2CF_3$ ;  $R_2 = -m(p)C_6H_4-$  have higher permeability for CO<sub>2</sub> than for other gases. This is explained by the ability of the CO<sub>2</sub> quadrupole to have specific interactions with polar groups and aromatic nuclei. Thus, in the case of polymers having  $-CH_2-CH_2-CF_3$  side groups, the high solubility of CO<sub>2</sub> results from dipole-dipole interaction of CO<sub>2</sub> molecules with the electronegative atom of fluorine.

Variation in the structure of the organosilicon polymer has a much stronger effect on the diffusion component of permeability than on the sorption component (see Table 9.3). For example, the increase in glass transition temperature from  $T_g = -123^\circ\text{C}$  in the case of polydimethylsiloxane (PDMS), to  $T_g = -28^\circ\text{C}$ , in the case of polymethylphenylsiloxane, results in reduction of the diffusion coefficient of propane from  $10.1 \times 10^{-6}$  to  $0.29 \times 10^{-6}$  cm<sup>2</sup>/s, i.e., by a factor of more than 30, whereas the sorption coefficient of propane changes from  $8.49 \times 10^{-2}$  to  $4.87 \times 10^{-2}$  cm<sup>3</sup>/cm<sup>3</sup> cm Hg, i.e., by a factor of  $<2$ .

**FIGURE 9.9** Dependence of permeability coefficients of methane, ethane, and propane in various organosilicon polymers on the glass transition temperature of the polymer: (a) —(CH<sub>3</sub>)<sub>2</sub>Si—O—; (b) —(CH<sub>3</sub>)(C<sub>2</sub>H<sub>5</sub>)Si—O—; (c) —(CH<sub>3</sub>)(C<sub>3</sub>H<sub>7</sub>)Si—O—; (d) —(CH<sub>3</sub>)(C<sub>8</sub>H<sub>17</sub>)Si—O—; (e) —(CH<sub>3</sub>)(CF<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>)Si—O—; (f) —(CH<sub>3</sub>)(C<sub>6</sub>H<sub>5</sub>)Si—O—; (g) —(CH<sub>3</sub>)<sub>2</sub>Si—CH<sub>2</sub>—; (h) —(CH<sub>3</sub>)<sub>2</sub>Si—(CH<sub>2</sub>)<sub>2</sub>—(CH<sub>3</sub>)<sub>2</sub>Si—O—; (i) —(CH<sub>3</sub>)<sub>2</sub>Si—(CH<sub>2</sub>)<sub>6</sub>—(CH<sub>3</sub>)<sub>2</sub>Si—O—; (j) —(CH<sub>3</sub>)<sub>2</sub>Si—(CH<sub>2</sub>)<sub>8</sub>—(CH<sub>3</sub>)<sub>2</sub>Si—O—; (k) —(CH<sub>3</sub>)<sub>2</sub>Si—*m*C<sub>6</sub>H<sub>4</sub>—(CH<sub>3</sub>)<sub>2</sub>Si—O—; and (l) —(CH<sub>3</sub>)<sub>2</sub>Si—*p*C<sub>6</sub>H<sub>4</sub>—(CH<sub>3</sub>)<sub>2</sub>Si—O—. **FIGURE 9.10** Dependence of ideal hydrocarbon/nitrogen permselectivity on the boiling temperature of the hydrocarbons for a polyorganosilicon membrane produced by GKSS [39–43]. (From Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

The permselectivity of hydrocarbon vapors,  $\alpha_p$ , is dominated by the sorption component, and sorption of hydrocarbon vapors by rubbery polymers is determined by the condensability of their vapors. It can be seen from Table 9.3, that in organosilicon polymers the propane/methane sorption selectivity,  $\alpha_s$ , is 10.5–16.2, whereas diffusion selectivity,  $\alpha_D$ , is only 0.16–0.41. Refs. [39–43] report values of permselectivity of hydrocarbon mixtures with nitrogen for organosilicon membranes produced by GKSS (see Figure 9.10). It can be seen that separation selectivity increases with rising boiling temperature of the hydrocarbon, which points to domination of the sorption component of selectivity.

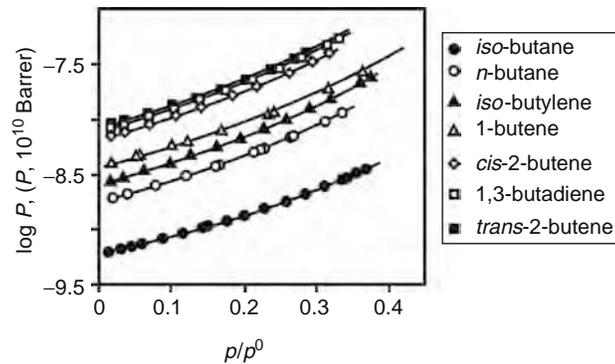

### 9.3.1.2 Pressure Dependence of Hydrocarbon Permeability in Rubbery Polymers: Effect of Plasticization of the Polymer by the Penetrant

With the increase in relative pressure of hydrocarbon vapor, i.e., with the increase in its activity, the plasticizing effect on the polymer becomes stronger, resulting in the increase in permeability (see Figures 9.11 and 9.12; Table 9.2).

Investigation of a wide range of block copolymers, consisting of various flexible (polydimethylsiloxane, polybutadiene) and rigid (polycarbonate, polysulphone, polyarylate) phases [44], shows that irrespective of the chemical nature of copolymer, content and molecular weight of blocks as well as pressure and composition of the hydrocarbon mixture, sorption, and mass transfer of alkanes take place primarily in the rubbery phase. The phenomenon of plasticization of polymers by hydrocarbons was demonstrated by baromechanical methods [7,45–48]. Figure 9.13 shows baromechanical curves for the block copolymer

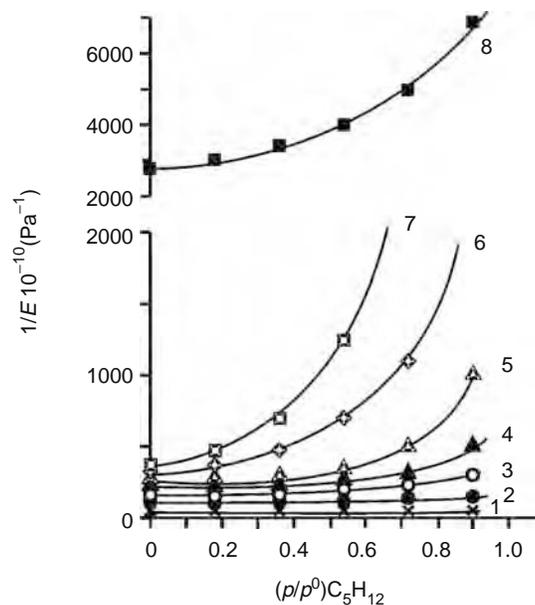

**FIGURE 9.11** Dependence of permeability coefficients of methane, ethane, and propane in polydimethylsiloxane on the corresponding hydrocarbon activity. (From analysis of results presented in Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

**FIGURE 9.12** Dependence of permeability coefficients of individual hydrocarbons in polybutadiene on the corresponding hydrocarbon activity. (From Kamiya, Y., Terada, K., Naito, Y., and Wang, J.S., *J. Polym. Sci.*, B33, 1663, 1995.)

Sulfosil (polysulfone/polydimethylsiloxane) in pentane vapor for various levels of polydimethylsiloxane content. By analyzing these curves, the effect of the flexible/rigid phase ratio on mechanical properties of the block copolymer in the plasticizing vapor environment can be considered. Block copolymers having PDMS content <50 wt% display a minor increase in elastic compliance (which is the reciprocal value of elasticity modulus,  $E$ ). If the flexible phase content is more than 50%, elastic compliance smoothly increases with pentane activity. Analysis of the dependence of the block copolymer's elasticity modulus in vacuum on the composition of the block copolymer shows that phase inversion is completed around 55 wt% PDMS. Specifically, the rigid phase is continuous if PDMS content is below 50 wt%, and the flexible phase is continuous if PDMS content is above 50 wt%. It is therefore clear that block copolymer plasticization is mainly caused by PDMS phase plasticization. Increased elastic compliance of block copolymer is particularly noticeable if flexible phase content exceeds 50 wt%. It has been established that the nature of the rigid phase has a negligible effect on the elasticity modulus of block copolymers in saturated hydrocarbon environment [44]. Elastic compliance of block copolymers in the region of low values of the volume fraction  $\varphi$  of the hydrocarbon, dissolved in the block copolymer (with  $\varphi < 0.3$ , which corresponds to hydrocarbon vapor activity  $\sim 0.8$ ) can be described by the equation:  $1/E = k\varphi$ , where  $k$  is the coefficient of proportionality for the sorbed hydrocarbon. Thus, elastic compliance is directly proportional to the volume fraction of the sorbate, coefficient  $k$  increasing with thermodynamic affinity of the system. Values of ideal selectivity  $\alpha_p^{\text{id}} = P_{\text{Ci}}/P_{\text{C1}}$  were calculated from data of transfer of individual alkanes. With increasing

**FIGURE 9.13** Elastic compliance vs  $n$ -pentane relative pressure curves (baromechanical curves) for block-copolymer sulfosil (polysulfone/polydimethylsiloxane) for various polydimethylsiloxane contents (wt%): (1) 0; (2) 16; (3) 22; (4) 42; (5) 50; (6) 55; (7) 63; (8) 80.  $T = 293$  K. (From Sidorenko, V.M., *Membrane Separation of Hydrocarbons of Oil and Natural Gases*. PhD dissertation. Vladimir, NPO "Polimersintez", 1991, in Russian.)

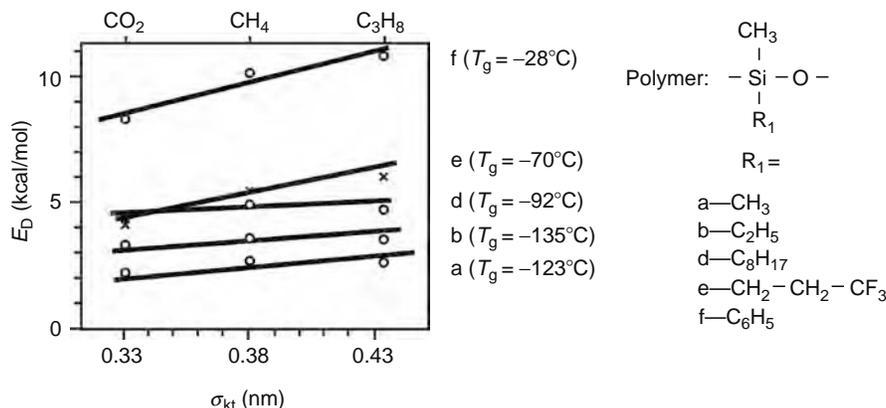

molecular weight of the hydrocarbon, the concentration dependence of  $\alpha_p^{\text{id}}$  becomes more pronounced. High values of selectivity of *n*-alkanes, which noticeably rise in the sequence C<sub>2</sub>–C<sub>4</sub> and achieve the order of magnitude of 10<sup>2</sup> in the case of *n*-butane, point to the possibility of using siloxane-containing block copolymers to separate vapor–gas mixtures of saturated hydrocarbons.

### 9.3.1.3 Temperature Dependence of Hydrocarbon Permeability in Rubbery Polymers

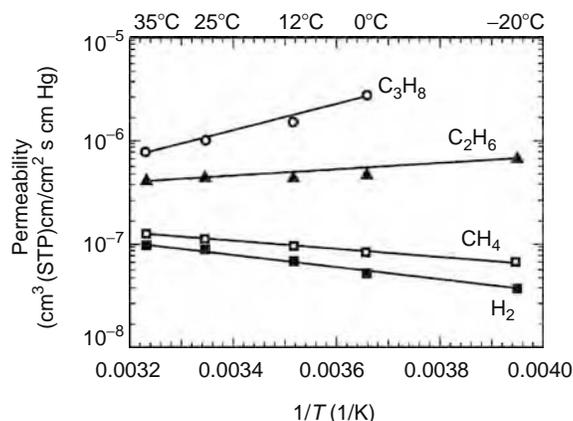

Semenova et al. [7,49–52] show that for gases and vapors strongly sorbed by polymers, non-monotonic temperature dependences of mass transfer coefficients are observed. This results from negative heat of penetrant sorption and plasticization of the polymer by the penetrant in the course of sorption. Negative heat of penetrant sorption can be caused by its specific interaction with the polymer as well as high values of condensation heat, which is typical of easily condensable hydrocarbons. The possibility of existence of non-monotonic temperature dependencies of mass transfer coefficients is demonstrated and corroborating experimental data are presented for penetrants interacting with polymer membranes in a specific way. It has been demonstrated, among other things, that in the case of variation of temperature, at constant concentration (pressure) of a strongly sorbable penetrant in the polymer, the condition for existence of a temperature corresponding to the minimum value of diffusion coefficient,  $T_{\text{min}}(D)$ , is a negative value of sorption heat  $\Delta H_s$ , and for emergence of a temperature corresponding to the minimum value of permeability  $T_{\text{min}}(P)$ , an additional condition should be met:  $|E_D| > |\Delta H_s|$ , where  $E_D$  is diffusion activation energy. It has been established that since at  $\Delta H_s < 0$   $E_D > E_D + \Delta H_s$  (because the diffusion activation energy is an essentially positive quantity),  $T_{\text{min}}(D) < T_{\text{min}}(P)$  is observed, i.e., the minimum point in the permeability curve  $P(1/T)$  is shifted with respect to the minimum point in the diffusion curve  $D(1/T)$  toward higher temperatures. In the curves showing the dependence of selectivity on temperature at constant penetrant pressure  $\alpha_p(T)_p$  as well as in curves showing the dependence of selectivity on penetrant pressure at constant temperature  $\alpha_p(p)_T$ , emergence of maxima is possible. These conclusions are quite important for selection of an optimum mode of using the membranes. Theoretical findings of Refs. [7,52] experimentally corroborated for interacting polymer–penetrant systems can certainly be applied to systems consisting of a polymer and an easily condensable hydrocarbon. Unfortunately, sufficient experimental data corroborating this conclusion are not yet available in the literature.

As reported in studies by Stern et al. [20,34–37], permeation coefficients of hydrocarbons in organosilicon polymers, including PDMS, change monotonically (decreasing in the case of propane and increasing in the case of methane) with rising temperature from 10°C to 55°C. For methane penetrating through PDMS,  $E_D \sim 12$  kJ/mol,  $\Delta H_s \sim -8$  kJ/mol whereas for propane  $E_D \sim 12$  kJ/mol,  $\Delta H_s \sim -18$  kJ/mol. That is, the condition  $|E_D| > |\Delta H_s|$  holds for methane and an extreme temperature dependence of permeability can be discovered for methane. Figure 9.14 shows the dependence of the values of diffusion activation energies for several polymers on the kinetic diameter of the penetrant molecule. It can be seen that diffusion activation energy increases with the kinetic diameter of the penetrant molecule and the more rigid is the polymer (i.e., the higher is its glass transition temperature), the stronger is this dependence. Analysis of the data reported in Refs. [34–37] shows that propane permeability is observed in organosilicon polymers with different glass transition temperatures, while the condition  $|E_D| > |\Delta H_s|$  holds for organosilicon polymers with glass temperature  $T_g > 185$  K. Extreme temperature dependence of propane permeability can be found for these polymers.

Gas permeabilities of isotropic PDMS films were determined over a temperature range of 35°C to –20°C for pure gases and a series of binary *n*-butane/methane and multicomponent hydrocarbons/hydrogen mixtures [38]. Pure-gas permeabilities in PDMS as a function of reciprocal temperature are presented in Figure 9.15. It can be seen that the decrease in temperature

**FIGURE 9.14** Dependence of the diffusion activation energy of carbon dioxide, methane, and propane in organosilicon polymers on the kinetic diameter of the penetrant molecules (designations of polymers are the same as in Figure 9.9). (From analysis of results presented in Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

**FIGURE 9.15** Pure-gas permeabilities of an isotropic PDMS film as a function of reciprocal temperature. Feed pressure: 4.4 atm; permeate pressure: 1 atm. (From Pinnau, I. and He, Z., *J. Membr. Sci.*, 244, 227, 2004. With permission.)

results in a monotonic increase in permeability of ethane and propane and a decrease in permeability of methane and hydrogen. There is no turning point in Figure 9.15, but for methane it can be below  $-20^{\circ}\text{C}$ , i.e., beyond the considered temperature range. The permeabilities of all gas mixture components depend strongly on feed gas composition and temperature. An increase in organic vapor concentration, at constant feed pressure and temperature, leads to increased chain mobility in PDMS, and, consequently, higher diffusivity and permeability. The relative increase in permeability is higher for large, condensable vapors, such as *n*-butane, than for small, permanent gases, such as hydrogen or methane. As a result, selectivities for mixed gas hydrocarbon/methane and hydrocarbon/hydrogen increase with the increase in feed vapor concentration. A decrease in feed temperature also results in higher organic vapor permeability and vapor/permanent-gas selectivity. The mixed gas *n*-butane/methane selectivity of PDMS film increased from 9°C at  $35^{\circ}\text{C}$ , to 25°C at  $-20^{\circ}\text{C}$  using a binary feed mixture containing 2 vol% *n*-butane in methane.

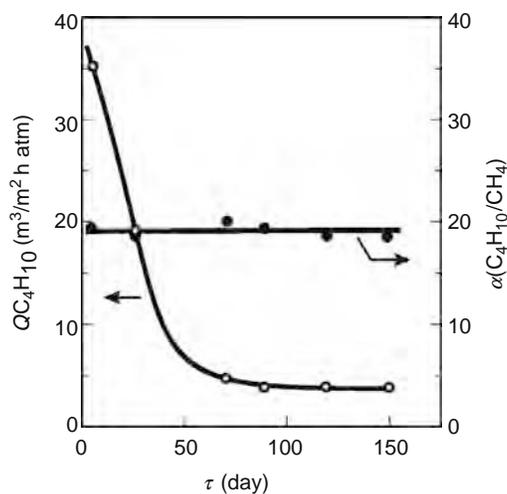

#### 9.3.1.4 Polytrimethylsilylpropyne as a Membrane Material for Hydrocarbons Separation and Removal from Gas Mixtures

PTMSP is a unique glassy polymer with glass transition temperature  $T_g$  of  $>250^{\circ}\text{C}$ . Because of its stiff backbone, in combination with the bulky  $-\text{Si}(\text{CH}_3)_3$  side group, PTMSP is known to have a fairly high fractional free volume of  $\geq 25\%$ . The gas permeability coefficients of PTMSP are one order of magnitude higher than those of PDMS. Butane/methane selectivity of PTMSP is higher in mixed gas measurements (at 10 atm,  $35^{\circ}\text{C}$ , 3% butane) than the ideal selectivity measured with single gases  $\alpha^{\text{mix}} = 27$ ,  $\alpha^{\text{id}} = 3.5$ . For PDMS the values are  $\alpha^{\text{mix}} = 5$ ,  $\alpha^{\text{id}} = 16.5$  [53]. It has been shown that butane condenses in the pores of PTMSP. Surface diffusion and diffusion of methane through pores filled with condensate are hindered. Condensed butane, however, does not inhibit significantly the transport of butane molecules. Consequently, only the flux of methane is reduced by the presence of butane while the flux of butane remains almost unaffected.

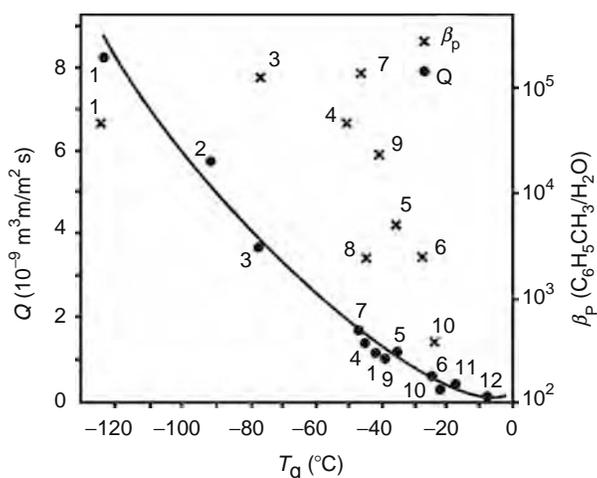

Unfortunately there is an aging problem for PTMSP, resulting in deterioration of its transport properties with time. As shown in Figure 9.16, permeability decreased by one order of magnitude during the first 3 months, whereupon permeability stabilized. Selectivity remained stable during this period. But even the aged PTMSP is still a viable alternative to rubbery polymers for heavy hydrocarbon removal.

#### 9.3.2 APPLICATION OF RUBBERY POLYMERS FOR PERVAPORATION REMOVAL OF HYDROCARBONS FROM THEIR AQUEOUS SOLUTIONS

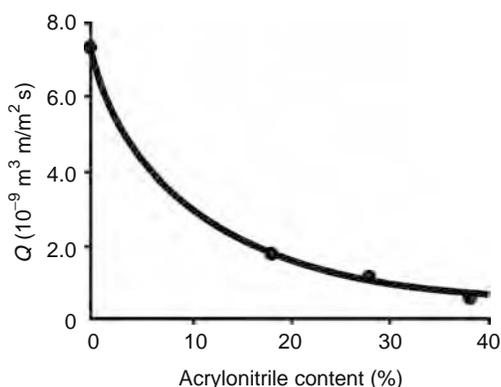

The need for removal of hydrocarbons from their aqueous solutions and emulsions generated in a large number of processes is accounted for by both economical and environment protection considerations. One possible way of solving this problem is pervaporation separation of water–organic mixtures. The materials used to make membranes for these applications are rubbery polymers. Nijhuis et al. [54] investigated pervaporation properties of several rubbery polymers with respect to the saturated toluene/water mixture. It has been established that with the increase in the glass transition temperature of the polymer, i.e., with the increase in its rigidity, a decrease in permeability is observed. The separation factor also decreases, although the latter dependence is not very strict, probably due to the swelling of the membrane (see Figure 9.17). With an increase in the content of nitrile groups in nitrile butadiene rubber, a decrease in permeability is also observed, because rigidity of the polymer increases with the increase in the content of polar groups (see Figure 9.18). Effectiveness of pervaporation removal of organic substances, including hydrocarbons, from water–organic mixtures is determined by both sorption and diffusion components of the separation factor. With an increase in the sorption component, affinity of the polymer for the organic component increases,

**FIGURE 9.16** Aging effects of PTMSP during storage at ambient conditions:  $\circ$  butane flux and  $\bullet$  selectivity (measurements were made at 10 atm, 35°C, for methane/butane mixture with 3% butane; composite membrane had the selective layers 3–5  $\mu\text{m}$ ). (From Schultz, J. and Peinemann, K.V., *J. Membr. Sci.*, 110, 37, 1996. With permission.)

**FIGURE 9.17** Dependence of productivity and separation factor  $\beta_P$   $\text{C}_6\text{H}_5\text{CH}_3/\text{H}_2\text{O}$  of membranes based on various rubbery polymers on the glass transition temperature of the polymer (pervaporation separation of saturated toluene/water mixture,  $T = 308$  K): (1) polydimethyl siloxane; (2) polybutadiene; (3) polyoctylmethyl siloxane; (4) nitrile butadiene rubber with 18% mol of nitrile groups; (5) the same, 28% mol of nitrile groups; (6) the same, 38% mol of nitrile groups; (7) ethylene/propylene copolymer; (8) polyepichlorohydrin; (9) polychloroprene; (10) polyurethane; (11) polyacrylate rubber; (12) fluorocarbon elastomer. (From analysis of data presented in Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

**FIGURE 9.18** Dependence of productivity of membranes based on nitrile butadiene rubber on content of nitrile groups (pervaporation separation of saturated toluene/water mixture,  $T = 308$  K). (From Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

as a result the swelling of the polymer is enhanced, which can result in reduction of the diffusion component of the separation factor. This issue is quite complicated and deserves separate consideration [55].

In selective separation of hydrocarbons from their mixtures with air or from their aqueous solutions, it makes sense to use membranes based on rubbery polymers, whose permeability increases with the decrease in glass transition point. Permselectivity of rubbery polymers is dominated by the sorption component, which increases with condensability of the hydrocarbon penetrant. Higher activity of the component being separated in the feed mixture results in plasticization of the membrane and can make it swell. This can produce a non-monotonic dependence of selective properties of the membrane on activity of the component being separated. As a rule, permselectivity for mixtures of penetrants is significantly lower than their ideal values. Negative values of sorption heat of easily condensable hydrocarbons can result in existence of non-monotonic temperature dependencies of mass transfer coefficients.

## 9.4 SEPARATION AND REMOVAL OF HYDROCARBONS USING MEMBRANES BASED ON GLASSY POLYMERS

### 9.4.1 SEPARATION OF OLEFINS AND PARAFFINS

Ethylene is found in coke-oven gas (3–5 vol%), gases resulting from oil processing, e.g., cracking (up to 20 vol%). It is produced by pyrolysis of liquid distillates of oil or lower paraffin hydrocarbons (ethane, propane, and butane), or by dehydration of ethanol. Ethylene is used to produce polyethylene and its copolymers, oxides of ethylene, ethanol, ethyl benzene, acetaldehyde, vinyl chloride, and vinyl acetate. Propylene is used as feedstock in the production of polypropylene, acrylonitrile, propylene oxide, allyl chloride, acrolein, acrylic acid and its ethers/esters, cumene, butanols. Propylene is one of the products of catalytic cracking of liquid hydrocarbon waste products. It is also produced by dehydrogenation of propane. 1,3-butadiene is produced by catalytic dehydration of butane and *n*-butylenes present in natural gas and gas resulting from oil processing, as a side product of ethylene production by pyrolysis of oil stock or by catalytic decomposition of ethanol. Propylene is used in the production of rubbers and plastics.

It is very difficult to separate the mixtures of olefins and paraffins produced in the above processes because of similar physical properties of the vapors. To solve this problem, the membrane method holds much promise. When using this method the correct choice of the membrane material is very important.

#### 9.4.1.1 Effect of Unsaturated Bonds on the Size of Olefin Molecules and on the Capability of Olefins to Enter into Specific Interactions with the Membrane Matrix

In membrane separation of the olefin/paraffin mixture, the predominant selective separation of the olefin is evident. First, the olefin molecule is smaller in size compared to the respective paraffin. Specifically, C—C distance in paraffins is 0.1534 nm, whereas the C=C distance in olefins is 0.1337 nm. Atoms of carbon in paraffins feature  $sp^3$  hybridization and free rotation around C—C bonds. Atoms of olefins feature  $sp^2$  hybridization. The rigid C=C bond impedes internal rotation in the olefin molecule and makes it flat. It is therefore clear why olefin molecules are smaller in size compared to paraffin and why the diffusion coefficients of olefins in polymers would be higher than those of paraffins. Second, the presence of unsaturated bonds in olefin molecules makes them capable of specific interactions with the membrane matrix. Efforts to take advantage of these capabilities resulted in the development of an important field of research: facilitated transport.

Several studies are concerned with the problem of separating olefins and paraffins using membrane technology, including facilitated transport using liquid membranes or ion-exchange charged membranes containing ions of transition metals as complexing agents [56–65]. It is known that olefins are capable of reversible complexing with transition metals, containing d-orbitals. The nature of this interaction was first explained by Dewar in 1951 in terms of molecular orbital theory. Dewar postulated that the interaction with the atomic orbitals of the olefin determines the stability of the complex formed. In the course of complexing, metal and olefin act as electron donor and electron acceptor, respectively.  $\sigma$  is the bond component in the complex that is formed as a result of overlapping between external s-orbitals of the metal and the bonding  $\pi$ -molecular orbital of the olefin (in the case of positively charged metal ions the absent valent s-electrons can be regarded as a vacant s-orbital).  $\pi$  is the bond component in the complex that is formed as a result of transfer of electrons from the completely filled d-atomic metal orbital to the vacant antibonding  $\pi^*$  molecular orbital of the olefin. In assessing the possible use of complexing agents for selective separation of olefins from gaseous mixtures, the price of the complexing agent and the strength of the complex formed should be considered. Such transition metals as Pt (II) and Pd (II) are expensive and form too strong complexes with olefins, whereas Cu (I) and Ag (I) are relatively cheap and form reversible complexes. Such membranes have very high olefin/paraffin selectivity (up to 200–300) and relatively high permeability to olefin. However, processes based on facilitated transport have several limitations, e.g., they should be carried out in saturated water vapor. In addition, there exists the serious problem of carrier aging. The use of membranes operating on the basis of facilitated transport for separation of olefins and paraffins is beyond the scope of this chapter and has been already considered in the literature [56–65] in sufficient detail. However, the

example of facilitated transfer shows that it is possible to achieve high values of permselectivity by exploiting specific interactions of olefins with the membrane matrix.

#### 9.4.1.2 Effect of Chemical Composition of Glassy Polymers on Their Gas Separation Properties to Hydrocarbons

Separation of olefins and paraffins using polymer membranes without carrier is dealt with in several reports [66–76]. Henley and Santos [66] investigated the permeability of polyethylene films and found that olefin flux and olefin/paraffin selectivity are very low. Ito and Hwang [67] as well as Sridhar and Khan [68] investigated permeability of derivatives of cellulose and established that ethyl cellulose is a good material for selective removal of olefins from its mixtures with saturated hydrocarbons. The use of polysulfone as a membrane material for separation of olefins and paraffins is also reported [67]. Table 9.4 presents transport properties of some glassy polymers with respect to propylene/propane mixtures, C<sub>3</sub>H<sub>6</sub>/C<sub>3</sub>H<sub>8</sub> [68]. It can be seen that among polymers listed in Table 9.4, polyphenylene oxide is the most selective whereas ethyl cellulose and polysulfone yield the highest flux. However, analysis of literature data shows that for the above purposes polyimides offer the highest fluxes and selectivities, closely followed by polyphenylene oxides. The properties of these polymers are discussed below. Ideal olefin/paraffin selectivity is three times higher in polyimides than in cellulose derivatives and polysulfone [69]. Permeability of various polymers to olefins rises with increasing free volume of the polymer; the process is accompanied by parallel reduction of ideal olefin/paraffin selectivity (see, e.g., the data in Figure 9.19). Let us consider these effects in more detail for the best known and promising polymer materials: polyimides and polyphenylene oxides.

**FIGURE 9.19** Dependence of permeability coefficient of propylene C<sub>3</sub>H<sub>6</sub> (●) and ideal selectivity propylene/propane  $\alpha_P^{\text{id}}$  (C<sub>3</sub>H<sub>6</sub>/C<sub>3</sub>H<sub>8</sub>) (○) in various polymers on the inverse molar fraction of free volume of the polymer: polyimides (1) 6FDA-TeMPD; (2) 6FDA-TrMPD; (3) 6FDA-DDBT; (4) 6FDA-ODA; (5) BPDA-TeMPD; (6) BPDA-TeMPD; (7) BPDA-ODA; (8) PPO—polyphenylene oxide; (9) P4MP—poly-4-methylpentene-1; (10) 1,2PB—polybutadiene; (11) PDMS—polydimethylsiloxane. #### 9.4.1.2.1 Polyimides as Membrane Materials for Separation of Olefins and Paraffins

Semenova [8] contains a detailed analysis of the relationship between chemical composition of polyimides and their separation properties. It is shown that the molar fraction of free volume of the polymer increases after introduction of bulky substituents into the elementary unit. It is therefore not surprising that the attention of researchers is focused on polyimides with bulky substituents, e.g., polyimides produced on the basis of such dianhydride as 6FDA-dianhydride 4,4'-hexafluoroisopropylidene of diphthalic acid (containing two bulky CF<sub>3</sub>-groups in the acid fragment) and such diamines as TrMPD-2,4,6-trimethyl-1,3-phenylenediamine (containing three CH<sub>3</sub>-groups in the amine fragment), TeMPD-2,3,5,6-tetramethyl-1,4-phenyldiamine (containing four CH<sub>3</sub>-groups in the amine fragment), 4APF-4,4'-hexafluoroisopropylidene dianiline (containing two bulky CF<sub>3</sub>-groups in the amine fragment), DDBT-dimethyl-3,7-diaminodiphenyl-thiophene-5,5'-dioxide (industrial product of Ube: a mixture of isomers having two methyl groups located differently in the phenyl nucleus, e.g., 63% in the 2,8-position, 33% in the 2,6-position, and 4% in the 4,6-position).

Molecules of olefin have  $\pi$ -electrons, and in an aromatic polyimide, charge transfer complexes can be formed.  $\pi$ -electrons of aromatic rings can interact with  $\pi$ -electrons of olefin. Intrinsic gas permeabilities, diffusivities, and solubilities of the olefin and paraffins in aromatic 6FDA-1,5NDA/TeMPD copolyimide (where 1,5NDA is 1,5-naphthalene diamine) were reported in Ref. [76]. Copolymers with higher 6FDA-1,5NDA compositions show a better packing density, which is most probably due to the enhanced interchain interactions resulting from the charge transfer complexes. The two benzene rings fused together in the naphthalene diamine moiety of the polyimide may actively promote electron transfer between electron-rich donor molecule and electron-deficient acceptor molecule. The four methyl groups in the TeMPD diamine moiety successfully inhibit dense chain packing and promote gas diffusivity and solubility.

*Permeability to Vapors of Ethylene and Ethane:* Table 9.5 shows values of mass transfer parameters of ethylene and ethane for 6FDA-TrMPD and BPDA-TeMPD polyimides (where BPDA is 3,3',4,4'-diphenyltetracarboxylic dianhydride), and Table 9.6, those for 6FDA-*m*PDA, 6FDA-*i*PDA, and 6FDA-4APF polyimides (*m*PDA—*meta*-phenylenediamine; *i*PDA-2,2'-bis(4-amino-phenyl) isopropane). It can be seen that the permeability of ethylene is higher compared with that of ethane. The ideal permselectivity in these polymers is  $\alpha_p^{id} C_2H_4/C_2H_6 = 2.9$ –4.4. The main contribution to the permeation selectivity is made by the diffusion selectivity. Thus, for 6FDA-TrMPD polyimide  $\alpha_D^{id} C_2H_4/C_2H_6 = 2.9$ , while the sorption selectivity is only  $\alpha_s^{id} C_2H_4/C_2H_6 = 1.0$ .

*Permeability to Vapors of Propylene and Propane:* It can be seen from the data shown in Figure 9.19 as well as Tables 9.6 and 9.7 that sufficiently high permeability to propylene and the highest values of ideal selectivity  $\alpha_p^{id} C_3H_6/C_3H_8$  are found in

polyimides of the composition 6FDA-TeMPD, 6FDA-TrMPD, 6FDA-DDBT, 6FDA-ODA, and BPDA-TeMPD (ODA, oxide aniline). Among polyimides, the highest flux to propylene is found in 6FDA-TeMPD polyimide ( $P_{C_3H_6} = 37$  Barrer at 323 K and propylene pressure  $P_{C_3H_6} = 2 \times 10^5$  Pa), and the highest selectivity to the propylene/propane system is found in 6FDA-DDBT polyimide ( $\alpha_P^{id} C_3H_6/C_3H_8 = 30$  at 323 K and pressure of individual components of  $2 \times 10^5$  Pa). Diffusion selectivity of polyimides is  $\alpha_D^{id} C_3H_6/C_3H_8 = 7-27$ , whereas sorption selectivity is much lower, only  $\alpha_S^{id} C_3H_6/C_3H_8 = 1.0-1.3$ .

*Permeability to Vapors of 1,3-Butadiene, C<sub>4</sub>H<sub>6</sub>, n-Butane, C<sub>4</sub>H<sub>10</sub>, and 1-Butene, C<sub>4</sub>H<sub>8</sub>*: Okamoto et al. [32] investigated the permeability of individual vapors of 1,3-butadiene and *n*-butane in some glassy polymers: in 6FDA-TrMPD, 6FDA-DDBT polyimides, and in polyphenylene oxide (see data presented in Table 9.8). The investigated polyimides had high permeability to 1,3-butadiene  $P_{C_4H_6} = 6.5-110$  Barrer, as well as high values of ideal permselectivity  $\alpha_P^{id} C_4H_6/C_4H_{10} = 67-190$  (at pressure  $1 \times 10^5$  Pa and 323 K). Diffusion selectivity was  $\alpha_D^{id} C_4H_6/C_4H_{10} = 45-110$ , whereas sorption selectivity is much lower and corresponds to only  $\alpha_S^{id} C_4H_6/C_4H_{10} = 1.5-1.7$ .

Shimazu et al. [70] investigated the permeability of 1,3-butadiene, *n*-butane, 1-butene in various glassy polymers, including polyimides based on 6FDA anhydride, notably 6FDA-*p*ODA and 6FDA-4APF polyimides. Figure 9.20 shows the dependence of ideal selectivity  $\alpha_P^{id} C_4H_6/C_4H_{10}$  and ideal selectivity  $\alpha_P^{id} C_4H_6/C_4H_8$  on the permeability of 1,3-butadiene. It can be seen that polymers having the highest permeability ( $P_{C_4H_6} = 10^2-10^3$  Barrer) and the highest selectivity ( $\alpha_P^{id} C_4H_6/C_4H_{10} = 10^4-10^5$  and  $\alpha_P^{id} C_4H_6/C_4H_8 = 10^3-10^4$ ) are polyimides based on 6FDA-dianhydride.

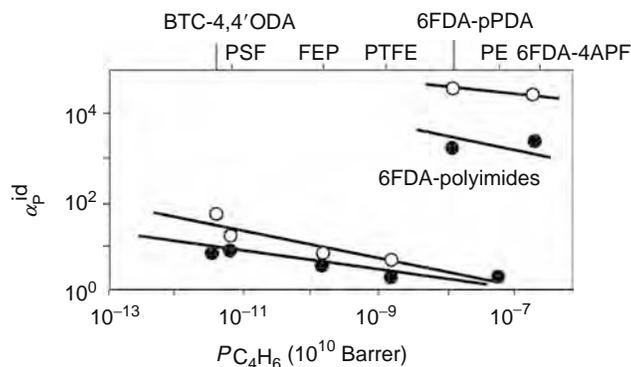

*Comparative Permeability of C<sub>2</sub>, C<sub>3</sub>, and C<sub>4</sub> olefins*: It is interesting to compare permeability, diffusion, and solubility coefficients of various olefins, as well as ideal olefin/paraffin selectivity in a glassy polymer. Such comparison can be made,

(PSF, polysulfone; FEP, Teflon; PTFE, polytetrafluoroethylene; PE, polyethylene; BTC, 4,4'ODA-polycarbonate). (From Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

e.g., for 6FDA-TrMPD polyimide, by analyzing its properties with respect to individual components, such as ethylene, propylene, and 1,3-butadiene (see Tables 9.5–9.8 as well as data presented in Refs. [9,32]).

The diffusion coefficients of olefins can be arranged in a series that is the reverse of the series of effective molecular diameters:  $d_{\text{ef,C}_2\text{H}_4} = 0.423 < d_{\text{ef,C}_4\text{H}_6} = 0.440 < d_{\text{ef,C}_3\text{H}_6} = 0.468 \text{ nm}$ ;  $D_{\text{C}_2\text{H}_4} = 390 > D_{\text{C}_4\text{H}_6} = 225 > D_{\text{C}_3\text{H}_6} = 130, 10^{-10} \text{ cm}^2/\text{s}$ . The boiling temperatures of olefins, reflecting condensability of olefins, can be arranged in a series that corresponds to the series of their solubility coefficients:  $T_{\text{b,C}_2\text{H}_4} = 169.5 < T_{\text{b,C}_3\text{H}_6} = 225.5 < T_{\text{b,C}_4\text{H}_6} = 282.2 \text{ K}$ ;  $S_{\text{C}_2\text{H}_4} = 0.15 < S_{\text{C}_3\text{H}_6} = 0.23 < S_{\text{C}_4\text{H}_6} = 0.41 \text{ cm}^3/\text{cm}^3 \text{ cm Hg}$ . On the basis of sequences reflecting the correspondence between diffusion and solubility coefficients, the series of permeability coefficients of olefins is quite explicable:  $P_{\text{C}_3\text{H}_6} = 30 < P_{\text{C}_2\text{H}_4} = 58 < P_{\text{C}_4\text{H}_6} = 92 \text{ Barrer}$ . The values of ideal olefin/paraffin selectivity can be arranged in the following series:  $\alpha_P^{\text{id}} (\text{C}_2\text{H}_4/\text{C}_2\text{H}_6) = 2.9 < \alpha_P^{\text{id}} (\text{C}_3\text{H}_6/\text{C}_3\text{H}_8) = 11 < \alpha_P^{\text{id}} (\text{C}_4\text{H}_6/\text{C}_4\text{H}_{10}) = 67$ .

#### 9.4.1.2.2 Polyphenylene Oxides as Membrane Materials for Separation of Olefins and Paraffins

Polyphenylene oxides are quite promising materials for separation and removal of olefins and paraffins. In terms of their properties these polymers are only inferior to polyimides (see Tables 9.7–9.9; Figures 9.19, 9.21, and 9.22).

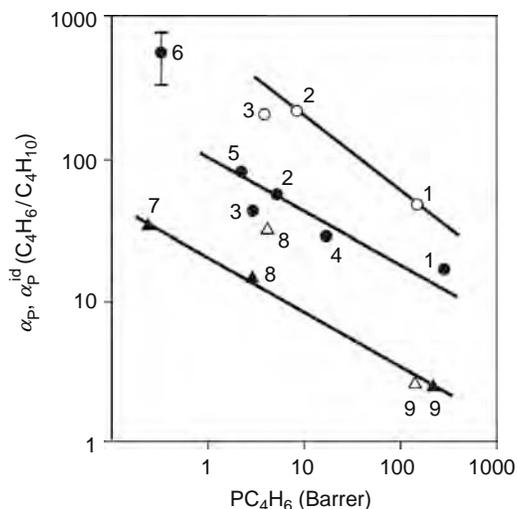

Separation properties of poly-2,6-dimethyl-1,4-phenylene oxide (p-DMePO) and poly-2,6-diphenyl-1,4-phenylene oxide (p-DPhPO), as well as chemically modified p-DMePO have been studied by a number of researchers for the purpose of using these polymers in gas separation and pervaporation processes [18,68,71]. p-DMePO/p-DPhPO copolymers offer a number of advantages compared to homopolymers: better mechanical properties, higher resistance to oxidants and radiation, which is why these copolymers have also been studied rather closely [18,71]. Investigation of p-DMePO and p-DPhPO homopolymers has

shown that side groups have a significant effect on free volume of the polymer and its transport properties. It has been established that the molar fraction of free volume of p-DPhPO having phenyl side groups is smaller than the molar fraction of free volume of p-DMePO having methyl side groups. Therefore permeability and diffusion coefficients of hydrocarbons in the p-DPhPO polymer are smaller compared to the p-DMePO polymer (see Figure 9.23). It is also not surprising that permeability and diffusion coefficients of hydrocarbons decrease with the increase in the content of the diphenyl-substituted component in the copolymer.

Thus, it follows from the above data that glassy polymers are promising materials for selective separation of olefins from their mixtures with paraffins. The main contribution to the high values of permselectivity is made by the diffusion component  $\alpha_D$ . However, unsaturated bonds in olefin molecules make them capable of specific interactions with  $\pi$ -conjugated polar

groups. Introduction of such groups into the polymer membrane would make it possible to significantly raise sorption selectivity  $\alpha_S$ . Unfortunately, research activity in this field is not sufficiently extensive.

#### 9.4.1.3 Pressure Dependence of Hydrocarbon Permeability and Selectivity in Glassy Polymers

Permeability coefficients of olefins and paraffins and olefin/paraffin selectivity coefficients in polymers are essentially dependent on partial pressure of the penetrants. Figure 9.24 shows the dependence of the permeability of 6FDA-TrMPD

**FIGURE 9.24** Dependence on pressure of permeability coefficients of propylene and propane for 6FDA-TrMPD polyimide ( $T = 323 \text{ K}$ ). (From Tanaka, K., Taguchi, A., Hao, J., Kita, H., and Okamoto, K., *J. Membr. Sci.*, 121, 197, 1996. With permission.)

**FIGURE 9.25** Dependence of permeability coefficients of propylene  $P_{C_3H_6}$ , propane  $P_{C_3H_8}$ , and selectivity on partial pressure for the equimolar gas mixture in 6FDA-TrMPD polyimide (total pressure  $3.1 \times 10^5$  Pa,  $T = 323$  K). For comparison, the corresponding data for individual components designated with open symbols. (From Tanaka, K., Taguchi, A., Hao, J., Kita, H., and Okamoto, K., *J. Membr. Sci.*, 121, 197, 1996. With permission.)

polyimide to such individual components as propane and propylene on their partial pressure. It can be seen from the figure that the permeability decreases until pressure reaches  $5 \times 10^5$  Pa, and then begins to rise. The reduction of permeability is explained by the dual-mode sorption model and is related to sorption sites of the polymer being filled by the penetrant. The increase in permeability at pressures above  $5 \times 10^5$  Pa is accounted for by plasticization of the polymer by the penetrant [9,32].

No  $C_2H_6$  and  $C_2H_4$  plasticization was detected for 6FDA-1,5NDA/TeMPD copolyimides even up to 16 atm [76]. However, plasticization was observed for  $C_3H_8$  and  $C_3H_6$  because of their high condensability and strong polymer-penetrant interactions. 6FDA-TeMPD has a lower plasticization pressure than 6FDA-1,5NDA for  $C_3H_8$  and  $C_3H_6$ . The plasticization pressures for the copolymers fall between the ranges of their parent homopolymer. The plasticization pressure is higher with an increase in 6FDA-1,5NDA content in these copolymers.

Permeability and diffusion coefficients of hydrocarbons in polyphenylene oxides are also essentially dependent on pressure (see Figure 9.23). It can be seen that in the case of ethylene, with the increase in pressure, the permeability coefficients first decrease, and then begin to rise. Ref. [18] quotes constants of the dual-mode sorption model for a number of hydrocarbons permeation through polyphenylene oxide.

Table 9.9 compares the separation properties of various polyimide to individual penetrants, propane and propylene, as well as their mixtures. Figure 9.25 shows dependencies of the permeability coefficients  $P_{C_3H_6}$  and  $P_{C_3H_8}$  and of the selectivity coefficient  $\alpha_P C_3H_6/C_3H_8$  for gaseous mixtures, as well as for individual penetrants, in 6FDA-TrMPD polyimide on partial pressure. Comparison of permeabilities of penetrants in the case of individual transport to those in the case of transport of an equimolar mixture (at equal partial pressure) shows that the permeability coefficient of propylene  $P_{C_3H_6}$  for mixtures is lower by 20%–30%, and the permeability coefficient of propane  $P_{C_3H_8}$  is higher by 10%–40% than those for individual penetrants. As a result, the selectivity in the mixture is much lower than the ideal selectivity [9]. Similarly, in the case of permeation of the  $C_4H_6/C_4H_{10}$  mixture through polyimides, the permeation selectivity is much lower than the ideal value which is also accounted for by the plasticization effect.

#### 9.4.1.4 Temperature Dependence of Hydrocarbon Permeability and Selectivity in Glassy Polymers

Theoretical findings of Refs. [7,52] experimentally corroborated for interacting polymer-penetrant systems can certainly be applied to systems consisting of a glassy polymer and an easily condensable hydrocarbon. Unfortunately, sufficient experimental data corroborating this conclusion are not yet available in the literature, although some regularities of variation of mass exchange properties as a function of temperature are considered in several reports [9,32]. Figure 9.22 shows dependencies of ideal selectivity  $\alpha_P^{id} C_3H_6/C_3H_8$  on permeability coefficient  $P_{C_3H_8}$  for polyimides and polyphenylene oxide at various

temperatures, and Table 9.10 lists values of permeability and diffusion activation energies, as well as heat of hydrocarbon sorption. It can be seen that the increase in temperature in the range 308–423 K is accompanied by an increase in the permeability and a decrease in the selectivity coefficient of the polymers. However, the existence of turning points is possible in a different range of temperatures and concentrations (see Section 9.3.1.3).

#### 9.4.1.5 Kinetics of the Permeation Process

Investigation of permeation of three-component hydrocarbon mixtures through polyphenylene oxides revealed a more complicated pattern compared to what is found by comparing permeabilities of individual gases. In a three-component mixture, the component having the highest penetration rate occupies free voids of the polymer ahead of other components, and is then gradually replaced by a more sorbable component from the occupied sorption sites [18]. It is known that sorption of an individual gas by a glassy polymer is higher than sorption of the same gas mixed with other gases. This effect results from competitive sorption [72,73]. Similarly, permeability of an individual gas through a glassy polymer is higher than that of the same gas penetrating in mixture with other gas. It has been established however that this applies only to the steady state. In the unsteady state the ratio of the diffusion coefficients of the penetrants plays an important role. Methane is the fastest and least sorbable component of the mixture. It occupies the microvoids of the polymer's free volume ahead of other components, as is clear from the kinetic permeability curves shown in Figure 9.26. This effect can be used to set up a pulse mode in the process of hydrocarbon separation.

**FIGURE 9.26** Time dependence of permeability coefficients for the mixture of gases  $CH_4/C_2H_4/C_2H_6$  (71%/19%/10% mol) for the membrane based on poly-2,6-dimethyl-1,4-phenylene oxide (pressure of the mixture  $5 \times 10^5$  Pa,  $T = 298$  K). (From Lapkin, A.A., Roschupkina, O.P., and Ilinitich, O.M., *J. Membr. Sci.*, 141, 223, 1998.)

## 9.4.2 SEPARATION OF AROMATIC, ALICYCLIC, AND ALIPHATIC HYDROCARBONS

### 9.4.2.1 Problem of Separation of Aromatic, Alicyclic, and Aliphatic Hydrocarbons

The separation of mixtures of aromatic, alicyclic, and aliphatic hydrocarbons, as well as their isomers, e.g., benzene and cyclohexane, toluene and iso-octane, and isomers of xylene has been actively developing in recent years. At present such separations are performed by fractional distillation, which is very energy expensive. In addition, this method cannot be used for separation of organic mixtures having similar boiling temperatures. Pervaporation is a good alternative in this case. Research in this area is mainly focused on development of membranes offering high-separation properties and good stability to the feed mixture [10,11,77–137].

#### 9.4.2.1.1 Aromatic–Alicyclic Hydrocarbons

Separation of benzene/cyclohexane mixture is investigated most extensively. This is not surprising because separation of this mixture is very important in practical terms. Benzene is used to produce a broad range of valuable chemical products: styrene (polystyrene plastics and synthetic rubber), phenol (phenolic resins), cyclohexane (nylon), aniline, maleic anhydride (polyester resins), alkylbenzenes and chlorobenzenes, drugs, dyes, plastics, and as a solvent. Cyclohexane is used as a solvent in the plastics industry and in the conversion of the intermediate cyclohexanone, a feedstock for nylon precursors such as adipic acid,  $\epsilon$ -caprolactam, and hexamethylenediamine. Cyclohexane is produced mainly by catalytic hydrogenation of benzene. The unreacted benzene is present in the reactor's effluent stream and must be removed for pure cyclohexane recovery.

A significant number of works are concerned with the development of new membranes for the separation of mixtures of aromatic/alicyclic hydrocarbons [10,11,77–109]. For example, the following works can be mentioned. A mixture of cellulose ester and polyphosphonate ester (50 wt%) was used for benzene/cyclohexane separation [113]. High values of the separation factor and flux were achieved (up to 2 kg/m<sup>2</sup> h). In order to achieve better fluxes and separation factors the attention was shifted to the modification of polymers by grafting technique. Grafted membranes were made of polyvinylidene fluoride with 4-vinyl pyridine or acrylic acid by irradiation [83]. 2-Hydroxy-3-(diethyl-amino) propyl methacrylate-styrene copolymer membranes with cyanuric chloride were prepared, which exhibited a superior separation factor  $\beta_P = 190$  for a feed aromatic component concentration of 20 wt%. Graft copolymer membranes based on 2-hydroxyethyl methacrylate-methylacrylate with thickness 10  $\mu\text{m}$  were prepared [85]. The membranes yielded a flux of 0.7 kg/m<sup>2</sup> h (for feed with 50 wt% of benzene) and excellent selectivity. Benzene concentration in permeate was about 100 wt%. A membrane based on polyvinyl alcohol and polyallyl amine was prepared [87]. For a feed containing 10 wt% of benzene the blend membrane yielded a flux of 1–3 kg/m<sup>2</sup> h and a separation factor of 62.

#### 9.4.2.1.2 Aromatic/Aliphatic-Aromatic Hydrocarbons

According to literary data, the following mixtures of aromatic/aliphatic-aromatic hydrocarbons were separated: toluene/*n*-hexane, toluene/*n*-heptane, toluene/*n*-octane, toluene/*i*-octane, benzene/*n*-hexane, benzene/*n*-heptane, benzene/toluene, and styrene/ethylbenzene [10,82,83,109–129]. As membrane media, various polymers were used: polyetherurethane, polyesterurethane, polyetherimide, sulfonyl-containing polyimide, ionically cross-linked copolymers of methyl, ethyl, *n*-butyl acrylate with acrylic acid. For example, when a composite polyetherimide-based membrane was used to separate a toluene (50 wt%)/*n*-octane mixture, the flux  $Q$  of 10 kg  $\mu\text{m}/\text{m}^2$  h and the separation factor of 70 were achieved [121]. When a composite membrane based on sulfonyl-containing polyimide was used to separate a toluene (1 wt%)/*n*-octane mixture, the flux  $Q$  of 1.1 kg  $\mu\text{m}/\text{m}^2$  h and the separation factor of 155 were achieved [10]. When a composite membrane based on ionically cross-linked copolymers of methyl, ethyl, *n*-butyl acrylate with acrylic acid was used to separate toluene (50 wt%)/*i*-octane mixture, the flux  $Q$  of 20–1000 kg  $\mu\text{m}/\text{m}^2$  h and the separation factor of 2.5–13 were achieved [126,127].

#### 9.4.2.1.3 Isomers

In oil processing, separation of aromatic isomers C<sub>8</sub> (ethylbenzene  $T_b = 136^\circ\text{C}$ , *p*-xylene  $T_b = 138.3^\circ\text{C}$ , *m*-xylene  $T_b = 139.1^\circ\text{C}$ , *o*-xylene  $T_b = 144.4^\circ\text{C}$ ) is required. According to the literary data, the following isomers of hydrocarbons are separated: *p*-xylene/*m*-xylene, *p*-xylene/*o*-xylene, *n*-hexane/2,2-dimethylbutane, *n*-hexane/3-methylpentane, and *n*-butane/*i*-butane [8,83,130–137]. Pervaporation method is the most effective for this purpose. To separate the isomers, membranes based on various polymers were used. Good separation for all isomer mixtures was attained by the polyimide Kapton film ( $\beta_P = 1.43$ –2.18) but parylene films and cellulose acetate also exhibited a relatively high separation factor ( $\beta_P = 1.22$ –1.56 and  $\beta_P = 1.23$ –1.56, respectively). Temperatures  $>200^\circ\text{C}$  were required to obtain a reasonable flux through the polyimide film and a pressure of about 20 atm was necessary to keep the feed stream liquid [8].

Thin films based on cellulose esters treated with an organic solvent were used for separation of isomeric xylenes, however, low values of factor  $\beta_P$  were achieved [130]. Modifications of hydrophylic membranes were used for separation of C<sub>8</sub>-aromatic isomers. Separation factor for *p*- to *m*-xylene was 1.69 [131]. Commercial polyvinyl alcohol membrane in the presence of CBr<sub>4</sub> as a selective feed complexing agent was used to separate *p*- to *m*-xylene [133]. Dense homogenous polyethylene membranes were used for separation of aromatic C<sub>8</sub>-isomers [132]. The rate of mass transport across the membrane increased

for the isomers in the order: *o*-xylene < ethylbenzene < *m*-xylene < *p*-xylene. The very small separation factors obtained restricted the use of polyvinyl alcohol membranes for purification of mixed xylenes on an industrial level. However, when a membrane based on polyvinyl alcohol filled with  $\beta$ -cyclodextrin was used to separate xylene isomers, the separation factor  $\beta_P$  of 2.96 was achieved [135].

The polymer materials mainly used for the membranes are glassy polymers, the first and foremost polyimides. The use of glassy polymers having a rigid ensemble of macromolecules results in high separation effectiveness. Separation effectiveness in pervaporation processes is characterized by the separation factor,  $\beta_P$ , which is determined by the diffusion component,  $\beta_D$ , and the sorption component,  $\beta_S$  [8,55]. Let us consider the effect of chemical composition of polymer membranes on their transport properties with respect to aromatic, alicyclic, aliphatic hydrocarbons and analyze ways to improve these properties.

#### 9.4.2.2 Diffusion Component of Separation Factor

This parameter is determined by the ratio of molecular sizes of the penetrants being separated and by rigidity and packing density of macromolecules. The greater the difference between molecular sizes of penetrants and the more dense and rigid the polymer matrix, the larger is the diffusion component of the separation factor [8,55].

##### 9.4.2.2.1 Dependence of Diffusion Component of Separation Factor on the Size of Penetrant Molecule

Section 9.2.2 deals with the issue of values of effective diameters of hydrocarbons penetrating through rubbery and glassy polymers (see Table 9.1). As shown in Refs. [10,11], when comparing sizes of differently shaped molecules it would be more correct to use as a criterion the minimum cross-section of the diffusing molecule  $a_D$  determined from Stuart's molecular model. This is especially important for oblong molecules, e.g., *n*-hexane and *n*-octane. It can be seen from the data presented in Table 9.1 that molecules of hydrocarbons can be arranged by the size of minimum cross-section in the following series: *n*-hexane  $\leq$  *n*-octane < benzene < toluene < cyclohexane < *iso*-octane. It is clear that the diffusion coefficients of these penetrants should vary in reverse order. This conclusion has been confirmed in Ref. [10] where the possibility of pervaporation separation of hydrocarbon mixtures using membranes based on DSDA-DDBT polyimide (DSDA, dianhydride of 3,3',4,4'-diphenylsulfonetetracarboxylic acid; DDBT, dimethyl-3,7-diaminobenzothiophene-5,5'-dioxide) has been investigated. Diffusion coefficients of the investigated hydrocarbons are indeed arranged in the series that is reverse to the series of minimum cross-sections of penetrant molecules. The membranes had preferential permeability for aromatic over aliphatic compounds. The strongest dependence of the separation factor and the permeability on the composition of the mixture being separated has been found in mixtures whose components display the greatest difference in molecular size.

Ref. [77] deals with the pervaporation separation of benzene/cyclohexane, toluene/*iso*-octane mixtures using DSDA-TrMPD/2,2'-diethynylbenzidine (DEB) copolyimide. The dominant role of the diffusion component  $\beta_D$  in the separation process has been established. It can be seen from the data in Table 9.11 that the increase in the difference between ratios of minimum cross-sections of penetrant molecules results in an increase of the separation factor  $\beta_P$  which is determined mainly by the diffusion component  $\beta_D$ .

##### 9.4.2.2.2 Factors Determining Rigidity of the Ensemble of Macromolecules

An important factor that determines diffusion selectivity of the membrane is the rigidity and regularity of the polymer structure and stability of the membrane to the mixture being separated. The rigidity of the polymer structure is determined

**TABLE 9.11**  
**Pervaporation Properties of the Membrane Based on DSDA-TrMPD/DEB Polyimide**

Composition of the mixture	$(\alpha_D)_{\text{arom}}/(\alpha_D)_{\text{al}}^a$ (nm/nm)	$Q_w$ (kg $\mu\text{m}/\text{m}^2\text{h}$ )	$\beta_P$ (Arom./Al.) <sup>b</sup>
Benzene/ <i>n</i> -hexane	0.21/0.18	2.8	9.1

by the make-up of individual macromolecules (primarily by potential barriers to rotation around intramolecular bonds) as well as the rigidity of the ensemble of macromolecules (primarily, strength of intra- and intermolecular interactions in the polymer). Intra- and intermolecular interactions in the polymer and between polymers produce a network of bonds, cross-links. Intermolecular interactions can be of various types, including dipole–dipole, dispersion interactions, hydrogen bonds, ion–ion interactions, as well as chemical and radiation cross-linking. In all cases cross-link density and strength of bonds in the cross-links, and, consequently, of the diameters of the diffusion channels in the polymer, are ultimately governed by the chemical structure of the polymer [8,55].

**9.4.2.2.3 Effect of the Increase in Rigidity of the Polymer System on the Diffusion Component of Separation Factor Thermal Cross-Linking of Unsaturated Bonds of Macromolecules:** Fang et al. [77] are concerned with the pervaporation properties, with respect to benzene/cyclohexane mixture being separated, of several ethynyl-containing copolyimides (the original composition for preparation of polyimides contained 2,2'-diethynylbenzidine) that were thermally cross-linked through unsaturated bonds. It can be seen from the data presented in Table 9.12 that the increase in the content of diethynylbenzidine (i.e., in the content of unsaturated bonds used for cross-linking) enhances the separation factor  $\beta_P$  (benzene/hexane). Table 9.12 also shows pervaporation properties of cross-linked and non-cross-linked DSDA-TrMPD/DEB polyimides. It can be seen that thermal cross-linking results in a nearly twofold increase in the diffusion component of the separation factor  $\beta_D$  with an insignificant change of the sorption component  $\beta_S$ .

**Increasing Cohesion Energy of the Polymer by Introducing Active Additives:** To increase the sorption component of the separation factor for the benzene/cyclohexane mixture, the matrix of DSDA-TrMPD/DEB polyimide was filled with a homogeneously distributed TCNE an electron acceptor having high affinity for ethynyl-containing fragments (DEB component in polyimide) and aromatic substances [77]. As a result, there was an increase not only in the sorption component (which will be discussed in Section 9.4.2.3) but also in the diffusion component of the separation factor  $\beta_D$  (see Table 9.12). This effect can be explained by the increase in rigidity of the polymer system as a result of the rise in cohesion energy after introduction of the additive, whose active groups display  $\pi$ -electron acceptor properties and can form charge transfer complexes with unsaturated fragments of macromolecules.

**Increasing Cohesion Energy of the Polymer by Introducing Polar Groups:** Introducing a polymer of polar groups with  $\pi$ -electron acceptor properties (such as ethynyl, phosphorylate, sulfone, acrylate, and phenyl groups) increases the cohesion energy of the polymer, which enhances the rigidity of the polymer ensemble, inhibits swelling, and thus increases the diffusion component of the separation factor [10,79–82]. For example, a series of copoly(methacrylates) with pendant phosphate and carboxylphosphonate groups were synthesized [109]. The copolymer membranes were cross-linked by the chemical reaction of either ethylene glycol diglycidyl ether or toluene diisocyanate with hydroxyl or secondary amine groups in copolymer segments. Although being in the rubbery state, the membranes displayed the behavior of low diffusion coefficient and positive aromatic/aliphatic diffusion separation factor ( $\beta_D$  up to 1.4 for benzene/*n*-hexane) and large activation energy of pervaporation, which has been observed in typical glassy polymers. This diffusion behavior can be explained by dense polymer-chain packing due to the hydrogen bonding between carbonyl and hydroxyl groups of polymer side-chain as well as relatively high cross-linking density. Pervaporation separation of toluene/*i*-octane mixtures using 6FDA-TrMPD/DABA copolyimide membranes

**FIGURE 9.27** Dependence of separation factor  $\beta_P$  (benzene/cyclohexane), as well as its diffusion component  $\beta_D$  based on styrene/butadienestyrene/acrylic acid copolymers on permeation flux (benzene/cyclohexane 50/50 wt% mixture,  $T = 293$  K). (From analysis of data presented in Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

containing 3,5-diaminobenzoic acid (DABA) was investigated in Ref. [128]. It was found that incorporation of the diamino-benzoic acid units promotes segmental packing, reduces membrane swelling, and improves the separation factor and durability of the membrane. The improvement in separation factor, with respect to the polymer without diaminobenzoic acid, is mainly due to the increase in the diffusion component  $\beta_D$ . It was established that the diffusion separation factor is exponentially correlated with the reciprocal of neat polyimide fractional free volume.

In addition, the polar groups enhance the affinity of the membrane for the aromatic component, as will be discussed below in Section 9.4.2.3.

*Increase in the Content of the Rigid Component of Copolymers:* Sun and Ruckenstein [78] deal with copolymers of styrene/butadiene and styrene/acrylic acid. Rigidity of the copolymer was regulated by changing the ratio of components. Rigidity of the copolymer is enhanced by the increase in cohesion energy, which is achieved by increasing the content of polar groups. This is accompanied by reduced permeability and enhanced benzene/cyclohexane separation factor, due to the increase in the diffusion component of separation factor up to  $\beta_D \approx 10$  (see Figure 9.27), while the sorption component of separation factor changes insignificantly:  $\beta_S \approx 1$ –1.3.

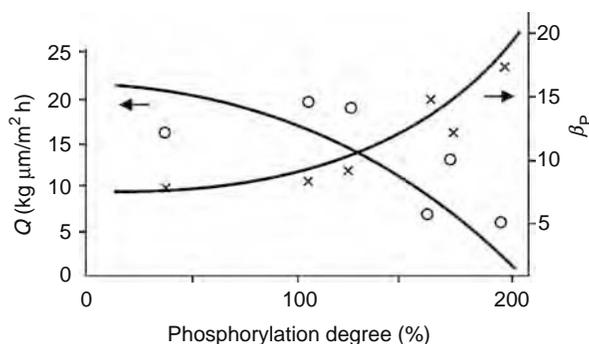

Tsubouchi and Yoshikawa [79] are concerned with pervaporation separation of benzene/cyclohexane mixtures using membranes based on polyamide/polyether block copolymers. It has been established that the separation factor increases with the increase in the polyamide component containing polar amide groups capable of forming hydrogen bonds: e.g., the 1:1 block copolymer of polyamide 12 and polyoxyethylene has the benzene/cyclohexane separation factor  $\beta_P = 2.8$  and the flux  $Q = 300$  g/m<sup>2</sup> h; a more rigid 3:1 polyamide 12/polyoxyethylene block copolymer has a much higher separation factor:  $\beta_P = 5.0$  and  $Q = 80$  g/m<sup>2</sup> h.

### 9.4.2.3 Sorption Component of Separation Factor

In the absence of specific penetrant/polymer interactions, the sorption component  $\beta_S$  is mainly determined by the ratio of boiling temperatures of the components being separated [8]. However, aromatic penetrants, as  $\pi$ -electron systems, can have specific interactions with active groups or fragments of the polymer. If such interactions are realized, the sorption component of the separation factor is increased. For selective removal of aromatic compounds from their mixtures with aliphatic and alicyclic compounds, the parameter  $\beta_S$  can be increased by introducing active groups or fragments having  $\pi$ -electron acceptor properties into the polymer. These groups or fragments have  $\pi$ -electron affinity for aromatic compounds (a charge transfer complex can be formed). These effects have been much investigated in polyimides.

#### 9.4.2.3.1 Increasing the Sorption Component of the Separation Factor by Introducing a Homogeneously Distributed Electron Acceptor into the Polyimide Matrix

To increase the sorption component of the separation factor, homogeneously distributed tetracyanoethylene, a strong electron acceptor having high affinity for electron donors, was added to the polyimide matrix [77]. It can be seen from data presented in Table 9.12 that this is accompanied by an increase in the sorption component  $\beta_S$  (benzene/cyclohexane) by a factor of 1.5 probably as a result of selective sorption of aromatic compounds by tetracyanoethylene with a simultaneous increase in the diffusion component  $\beta_D$ . The prepared membranes showed good pervaporation properties with respect to benzene/cyclohexane, toluene/isooctane mixtures. For example, for a two-component 50/50 wt% benzene/cyclohexane mixture at 343 K, the flux was  $Q = 0.44$  kg  $\mu\text{m}^2$  h, and  $\beta_P$  (benzene/cyclohexane) = 48; and for a two-component toluene/isooctane mixture, 45/55 wt%, at 343 K the flux was  $Q = 1.1$  kg  $\mu\text{m}^2$  h, and  $\beta_P$  (toluene/*iso*-octane) = 330.

**FIGURE 9.28** Dependence of productivity for the mixture (O) and separation factor of benzene/cyclohexane  $\beta_P(x)$  on degree of phosphorylation for phosphorylated and thermally cross-linked BPDA-TrMPD polyimides: benzene/cyclohexane, 50/50 wt% mixture,  $T = 343$  K, membrane thickness 30–40  $\mu\text{m}$ . (From analysis of data presented in Semenova, S.I., *J. Membr. Sci.*, 231, 189, 2004. With permission.)

#### 9.4.2.3.2 Increasing the Sorption Component of the Separation Factor by Introducing $\pi$ -Electron Acceptor Groups into the Polymer

**Ethynyl Groups:** According to Ref. [77], acetylene fragments introduced into polyimides, e.g., 2,2'-diethynylbenzidine, DEB, have  $\pi$ -electron affinity for aromatic compounds. It can be seen from the data presented in Table 9.12 that the increase in the content of DEB component results in an increase in the separation factor of the benzene/cyclohexane mixture. This is probably caused not only by the growth of the diffusion component  $\beta_D$  (resulting from thermal cross-linking through the unsaturated bonds) but also by enhancement of the sorption component  $\beta_S$ .

**Phosphorylate Groups:** Phosphorylate (phosphonate ester)- $\text{P}(\text{OC}_2\text{H}_5)_2 = \text{O}$  groups have high affinity for aromatic compounds [11,80,81,109]. It is known, e.g., that polymers with such groups are soluble in aromatic, but insoluble in aliphatic, hydrocarbons. Cabasso [80] reported good separation properties of polystyrene diethylphosphate for mixtures of aromatic, alicyclic, and aliphatic hydrocarbons. The separation factor of such membranes was  $\beta_P$  (benzene/cyclohexane) = 12–40 (50/50 wt% mixture, 351 K), and dependence of  $\beta_P$  on the degree of phosphorylation was observed. Ref. [11] deals with membranes based on glassy polymers such as BPDA-TrMPD polyimide, polystyrene, polyphenylene oxide, into whose molecules pendant phosphorylate groups were introduced by chemical modification (treatment with methylbromide followed by phosphorylation resulting from reaction with triethylphosphite). The degree of phosphorylation was up to 200%, i.e., up to two phosphorylate groups per recurrent unit of the polymer. Phosphorylated polyimide membranes were cross-linked thermally and then chemically with diamine. Sorption properties of the prepared polymers, as well as their pervaporation properties for separation of benzene/cyclohexane, benzene/hexane mixtures, were investigated. It has been established that pervaporation properties of modified polyimides depend on the degree of phosphorylation as well as on their degree of cross-linking. The increase in degree of phosphorylation is accompanied by an increase in the separation factor (see Figure 9.28). Compared to the original polyimide, the modified polyimide offers much better separation properties and higher stability to the feed mixture. High pervaporation selectivity of the modified polyimide is due to the presence of phosphorylate groups having high affinity for benzene. For the modified polyimide the sorption component of the separation factor for the benzene/cyclohexane mixture (at 343 K) was  $\beta_S = 6$ –9, whereas the diffusion component was only  $\beta_D = 2$ –3, and for the benzene/hexane mixture,  $\beta_D \approx 1$ . Pervaporation properties of membranes based on cross-linked phosphorylated polyimide are similar to those of membranes based on phosphorylated polystyrene and cellulose acetate.

Wang et al. [109] deal with pervaporation properties of cross-linked membranes of copoly(methacrylates) with pendant phosphate and carbamoylphosphonate groups with respect to aromatic/nonaromatic hydrocarbon mixtures. These groups have high affinity for aromatic hydrocarbons. The increase in the content of phosphorus in the polymer results in the growth of benzene sorption and of the sorption component of the separation factor (e.g., the content of phosphorus changed in the series  $0 < 8.6 < 9.6 < 10.2$  wt%, and the separation factor  $\beta_S$  changed accordingly:  $5 < 7.5 \approx 7.4 < 8.7$ ).

**Sulfone Groups:** It is known that sulfolanes are used for removal of aromatic components in petrochemical production processes. This prompted Hao et al. [10] to investigate sulphonyl-containing polyimides for pervaporation separation of aromatic and aliphatic hydrocarbons: DSDA-DDBT polyimide whose original acid component and original amine component both contained sulfone groups. DSDA-DDBT polyimide displays preferential sorption for aromatic, rather than aliphatic, penetrants. Thus, the amounts of sorbed benzene and toluene in this polyimide were 11 and 15 g, respectively, per 100 g of dry polymer, while the amount of sorbed aliphatic compounds was much lower. The investigated hydrocarbons can be arranged by increasing boiling temperature  $T_b$  in the series:  $n$ -octane > *iso*-octane > toluene > cyclohexane > benzene >  $n$ -hexane (see Table 9.1). In the absence of specific interactions, the sorption of these hydrocarbons should have been arranged similarly. However, the experimental sorption data follow a different series, beginning with aromatic penetrants: toluene > benzene >

*n*-hexane > *n*-octane > *iso*-octane > cyclohexane. This effect can be attributed to selective sorption of aromatic penetrants by sulfone groups. At 351 K, the content of benzene or toluene in the feed flow of the benzene (toluene)/cyclohexane mixture of 60/40 wt%, membrane flux was  $Q = 0.93 \text{ kg } \mu\text{m}^2/\text{h}$ , and the separation factor was  $\beta_P$  (benzene/cyclohexane) = 32; for toluene/*iso*-octane mixtures  $Q = 2.8 \text{ kg } \mu\text{m}^2/\text{h}$ ,  $\beta_P$  (toluene/*isooctane*) = 113.

*Acrylate Groups*: Wang et al. [82] prepared new membranes for separation of aromatic and aliphatic hydrocarbons mixtures by pervaporation. A porous film based on high-density polyethylene was used as support, onto which glycidinemethacrylate, having high affinity for aromatic penetrants, was grafted using various plasma treatment techniques. The prepared membranes displayed good separation properties: permeation flux was 0.30–0.37  $\text{kg}/\text{m}^2 \text{ h}$  and separation factor  $\beta_P$  (benzene/cyclohexane) was 19–22, for a 70/30 wt% composition of the mixture, at 344 K.

*Phenyl Groups*: Styrene has high affinity for aromatic compounds. However, membranes based on polystyrene cannot be used for separation of aromatic and nonaromatic hydrocarbons in practice; because good sorption of aromatic penetrants (much better than that of aliphatic ones) was accompanied by severe swelling with a consequent decrease in diffusion selectivity. It was proposed in Ref. [78] to use membranes prepared by emulsion polymerization of styrene and acrylic acid for separation of the benzene/cyclohexane mixture. The polymer in the disperse phase of the emulsion (polystyrene) swells well in the component being removed (benzene), whereas the polymer in the dispersion medium (acrylic acid which does not swell in either component) restricts membrane swelling and ensures a high separation factor. The flux through these membranes was  $Q = 450\text{--}800 \text{ g}/\text{m}^2 \text{ h}$ , with separation factor,  $\beta_P = 1.7\text{--}9.6$ , and its sorption component  $\beta_S = 1.10\text{--}1.35$  (50/50 wt% benzene/cyclohexane mixture, at 293 K). Reduction of the content of benzene in the feed mixture results in reduction of the flux through the membrane and a significant increase in  $\beta_S$ . Thus, for the 10/90 wt% composition of the benzene/cyclohexane mixture  $\beta_S$  is 1.5–2.5. With the increase in temperature the permeation flux increases and the separation factor decreases.

*Carboxylic Groups*: Pervaporation separation of toluene/*i*-octane mixtures using copolyimide membranes containing 3,5-diaminobenzoic acid (DABA) was investigated in Ref. [128]. It was established that introduction of diaminobenzoic acid into the 6FDA-TrMPD polyimide improves membrane selectivity. The sorption component of the separation factor  $\beta_S$  is linearly correlated with the membrane solubility parameter and with DABA content in the copolymer ( $\beta_S = 3.2, 3.3, 4.3, 5.2$  for DABA contents 0%, 10%, 33%, 60%, respectively).

*Carbon Graphite-Filled Membranes*: An attempt is made in Ref. [93] to improve pervaporation properties of membranes for selective separation of benzene/cyclohexane mixtures by exploiting  $\pi$ -interaction of the membrane and benzene. Carbon graphite was expected to show affinity for aromatics by using  $\pi$ -electron interaction. Novel membranes for pervaporation were prepared from carbon graphite and nylon. Benzene permeated preferentially over cyclohexane and the separation factor was  $\beta_P = 435$ ,  $\beta_S = 48$ , and  $\beta_D = 9.1$  at the weight fraction of benzene in the feed of 0.1. The sorption experiments made it clear that the introduction of carbon graphite into nylon enhances the solubility selectivity toward benzene and as a result, benzene preferentially permeated through the composite membranes.

The dependence of the aromatics/paraffin (or alicyclic hydrocarbon) separation factor on the activity of the hydrocarbon component being separated is not considered in detail in this chapter. This dependence can be non-monotonic as a result of membrane swelling. This issue deserves separate consideration. It should only be pointed out that such regularities are similar to those observed in hydrophilic membranes in selective separation of water from organics to water mixtures. The separation factor of hydrophilic membranes is strongly dependent on water activity in the feed mixture, and this dependence can be non-monotonic as a result of membrane swelling [55].

Thus, summarizing the above information, the following conclusion can be made. Selective separation of olefins and aromatic compounds from their mixtures with paraffins and alicyclic hydrocarbons can be quite effectively implemented using membranes based on rigid-chain glassy polymers, whose permselectivity is dominated by the diffusion component. Especially promising materials are polyimides with bulky substituents in both acid and amine fragments. Permselectivity of membranes with respect to olefins and aromatic compounds, whose molecules contain  $\pi$ -electron bonds (unsaturated bonds in olefins and delocalized  $\pi$ -bonds in aromatics) can be significantly improved by introduction into the polymer matrix of active groups with  $\pi$ -electron affinity having specific interactions with these bonds.

## 9.5 INDUSTRIAL REMOVAL OF HYDROCARBONS FROM THEIR MIXTURES WITH VARIOUS GASES AND VAPORS

Many industrial processes where hydrocarbons are used generate off gases containing vapors of hydrocarbons such as gasoline, naphtha, fuel, and solvents. If they are separated from the generated mixtures, these products constitute valuable chemical feedstock or fuel. However, if they are not separated, they become a source of environmental contamination.

Industrial separation of hydrocarbons from their mixtures with various gases, including air, is a specific case of a more general objective, separation of organic vapors from various gas/vapor mixtures. Early commercial vapor/gas membrane separation plants installed by Nitto Denko, MTR, GKSS were put into operation in 1988–1990. During the last 20 years, sales

of membrane gas separation equipment have been growing to become a \$150 million per year business. More than 90% of this business involves the separation of noncondensable gases (nitrogen from air, carbon dioxide from methane, hydrogen from nitrogen or methane, etc.). However, a much larger potential market for membrane gas separation is to be found in separating mixtures containing condensable gases such as the  $C_{3+}$  hydrocarbons [17,138,139].

To separate hydrocarbons from their mixtures with air, various process systems involving membranes are used. The choice of a particular setup is governed by its economic sensibility. To implement the technology:

- One- or two-stage process of membrane separation of hydrocarbons is used.
- Feed flow to be processed in the membrane unit is pressurized and vacuum is created downstream (on the permeate side).
- Combination of sorption, condensation, and membrane separation methods is used. Various sequences of these methods in the flowchart can be used according to the specific objective.

For example, the following sequence is typically used to separate gasoline vapors from a gasoline/air mixture [140]. A mixture of air and gasoline vapor, e.g., 40 vol%, is compressed to hundreds of millimeters of water and fed to the membrane unit. The downstream pressure is maintained by a vacuum pump at 60–100 torr. If the retentate contains <5 vol% gasoline, it is discharged into the atmosphere. The enriched permeate is fed to the absorber, where gasoline vapor is absorbed by a solvent, e.g., liquid gasoline, since absorption of gasoline vapor consisting of multicomponent mixtures of  $C_3$ – $C_7$  hydrocarbons by fresh liquid gasoline is quite effective. The resultant solution is reused in the process.

The problem of separating vapors of hydrocarbons with air occurs in treatment and transportation of oil products, in particular during filling gasoline to vehicles' tanks at filling stations, filling oil products to railroad tank cars and sea-going tankers. In all said cases there is huge loss of hydrocarbon vapors. For example, during a vehicle's filling the losses of evaporating gasoline are between 0.1% and 1%.

Losses of oil products during tank filling, storage, and vehicle refueling at gas stations can result from evaporations, spills, and spoilage. At gas stations, large volumes of oil products are typically discharged in small doses generating considerable evaporation losses. Evaporation losses can amount to 75%–80% of the total losses. Evaporation losses are caused by inadequate sealing of the process equipment, tanks and vehicles, as well as negligent handling. Gasoline has the highest evaporation losses compared to any other oil products because of higher vapor activity.

Two gasoline vapor recovery systems have been developed by GKSS to reduce gasoline vapor losses at gas stations: balance and vacuum systems [39–43,141]. The balance system has a mouth piece for gasoline discharge or intake, covered by a flexible hose. As a result, the connection between the fitting and filling pump is securely sealed. When the fuel is discharged to the tank of a vehicle, excess pressure is generated in it, pushing hydrocarbon vapors out. Negative pressure sucks the vapor into the empty area of an underground storage tank wherefrom gasoline is discharged. However, this process is difficult to control and therefore not always easy to implement. Efficiency of vapor recovery is about 70%–80% depending on the vehicle's make. The vacuum system is more efficient. Its efficiency can be as high as 99%. To return the hydrocarbon vapor to the storage tank special fittings are used on the device that fills the vehicle tank and meters the fuel feed. At a certain moment the vacuum pump of the membrane module is actuated. As a result of vacuum build-up the air valve in the return line is opened, producing excess pressure and creating feed flow to the membrane surface in the membrane module. Hydrocarbon vapors penetrate through the membrane and return to the storage tank. Exhausted hydrocarbon flow is discharged into the atmosphere.

The systems designed to reduce emissions during car refueling are commercialized under trade names VACONOVENT (supplier Borsig Membrane Gas Processing, Germany) and Permeator (supplier ARID Technologies, USA). More than 130 units have been installed worldwide. Test runs at a gas station in California showed a reduction of gasoline losses of 1,000 gal per month at monthly sales of 330,000 gal of gasoline (approximately 0.3%). Under more severe conditions at a demonstration unit in Shanghai, reduction of losses was 0.6% [141].

There are lots of gas, gas-condensate, and oil fields where the content of heavy fractions of hydrocarbons is quite high. Separation of heavy fractions of hydrocarbons at these fields not only facilitates their subsequent processing but also reduces the dew point, improving reliability, effectiveness, and safety of natural gas transportation to the consumer. Raw gas is usually almost saturated with respect to the heavy fractions of hydrocarbons and water vapor, which will condense at cold spots in the pipeline. To avoid condensation, the dew point of the gas is usually lowered to about  $-20^{\circ}\text{C}$  before being fed to the pipeline by removing propane, butane, and higher hydrocarbons. After compression and cooling to about  $30^{\circ}\text{C}$  by an air cooler, a portion of the water and  $C_{3+}$  hydrocarbons is condensed and recovered. The off-gas from the condenser is then processed using a silicone rubber membrane that preferentially lets through condensable vapors such as  $C_{3+}$  hydrocarbons and retains methane and ethane. The heavy hydrocarbons and the water-rich gas that permeate through the membrane are recycled to the front of the feed gas compressor. Water and  $C_{3+}$  hydrocarbons are eventually removed as condensed liquids. This process is at an early stage of commercialization [138,139]. The future growth of membrane gas separation technology will be in the refinery, petrochemical, and natural gas industries. Very large, untapped opportunities exist for membranes in all of these industries, and despite past failures, acceptance of membrane technology is increasing.

One of the most potentially successful and promising petrochemical applications is separation of the olefin/nitrogen mixture. In the process of polyolefin production, a mixture of olefin monomer (20%–50%) and nitrogen is formed. The compressed gas mixture is supplied to a condenser, where olefin portion is removed as a liquid. The remaining uncondensed olefin and nitrogen are separated in a membrane unit, which produces an olefin-enriched permeate and purified nitrogen stream (>98% nitrogen). The olefin-enriched permeate is recycled to the front of the compressor. The olefin liquid stream is upgraded in the monomer purification section of the plant and then recycled to the reactor [138,139].

Separation of mixtures of olefin vapors and paraffins should become a very promising market for membrane technologies. Mixtures of olefins and paraffins occur in several large-volume oil refining and organic synthesis processes, including the synthesis of polyethylene and polypropylene. For example, propane enters the process of polypropylene production as an impurity in the feed gas, which typically contains 99% propylene and about 1% propane. Unreacted propane builds up in the reactor to concentrations of 20–30 vol%. Propane build up is controlled by continually removing a fraction of the tank recycle stream as a purge, which is subsequently flared. Propane removal would significantly increase the output capacity of the polymerization process and the yield of the final product, polypropylene. This problem looks quite ripe for solution by membrane methods which would require the development of membranes offering propylene/propane selectivity of 3–5.

The separation of mixtures of aromatic, alicyclic, and aliphatic hydrocarbons, as well as their isomers, e.g., benzene and cyclohexane, toluene and iso-octane, isomers of xylene has an enormous potential market for membrane technologies. Membrane methods can be used, for example, in aromatic and alicyclic hydrocarbon production processes. Benzene is a component of all crude oils, it is present in the light oil recovered from coal carbonization gases. It is well known that benzene can be produced from toluene by transalkylation (toluene disproportionation), a process that also generates mixtures of xylenes. The production of benzene by reforming separation process is associated with the production of toluene and xylene (BTX plants). In the reforming separation process the aromatic fraction of crude oil is reformed catalytically to the BTX compounds being produced. Cyclohexane can be obtained by direct fractionation of crude gasoline cuts, by catalytic hydrogenation of benzene, and by distillation of naphtha. Separation of benzene and cyclohexane is a very important problem in the petrochemical industry. The unreacted benzene is present in the reactor's effluent stream and must be removed for pure cyclohexane recovery. Selective removal of aromatic components and separation of mixtures of hydrocarbons in all the above processes can be implemented by membrane methods.

By 2010, the total gas separation market is expected to be more than double to \$350 million and to double again by 2020 to \$760 million, an average growth rate of 7%–8% per year [138,139]. Much of this growth is to take place in new applications involving hydrocarbon vapors. Polymer membranes will undoubtedly be used to separate some of these gas mixtures, but new membranes ought to be made from new materials. In the last two decades thousands of new polymer materials were developed and their permeability with respect to various hydrocarbons was investigated. However, permeability and selectivity are only two of the criteria that must be met to produce a useful membrane. Others include the ability to form stable, thin, low-cost membranes that can be packaged into high-surface area modules. Successful industrial implementation of the above objectives would require further development of new polymer and hybrid membranes and membrane modules meeting all the above criteria.

## 10.1 INTRODUCTION

Various improvements have broadened the research in the field of zeolite membranes and films, such as the development of new synthesis procedures, the use of new supports with specific characteristics (monoliths, foams, etc.) or the use of modified supports by means of masking or grafting techniques, the application of new analytical techniques (isotopic-transient experiments, permoporometry, etc.), the control of the orientation of the crystals (by means of covalent linkages, synthesis conditions, etc.) and of the thickness of the membranes, and the preparation of new zeolites as membranes or new zeolite related-materials. In addition, a variety of zeolites can now be prepared as colloidal systems with particle dimensions ranging from tens to a few hundred nanometers.

Hence, their application field is not only restricted to use in gas separation, pervaporation, and membrane reactors but also applicable in microscale devices (microreactors and microseparators) and for the preparation of functional materials (adsorbents for trace removal, controlled release capsules, and chemical sensors).

This chapter gives an overview of the synthesis procedures and applications of zeolite membranes (gas separation, pervaporation, zeolite-membrane reactors), as well as new emerging applications in the micro- and nanotechnology field. Related areas such as new zeolite and zeolite-related materials for membranes, alternative supports, and scale-up issues are also discussed.

## 10.2 MEMBRANE SYNTHESIS AND CHARACTERIZATION

The term *zeolites* designates a variety of crystalline, hydrated aluminosilicates with a framework structure, which have been used for a long time as detergent builders (in view of their ion-exchange properties), adsorbents, and catalysts. However, since the early 1990s, an intensive research effort has been under way, aimed to the synthesis of zeolite membranes and to the development of separation applications, as is evidenced by large number of reviews recently published [1–6]. Among the 161 framework type codes assigned to date, by the International Zeolite Structure Commission, the most studied structures are MFI, LTA, FAU, MOR, and BEA.

Besides polymer-zeolite composites prepared by embedding zeolite crystals into a polymeric matrix (linked by means of interactions van der Waals or hydrogen bonds or by covalent linkages) and free-standing zeolite films (on temporal supports), the most common and industrially developed zeolite membranes are supported. The porous support introduces mechanical strength to the resulting membrane and allows the development of more extensive structures. Despite the clear advantage of supported zeolite membranes, there are three major disadvantages of using supports in the synthesis of zeolite membranes that make synthesis more difficult to reproduce: the support provides nucleation sites that are not present during homogeneous synthesis in the gel; the support itself can partially dissolve in the synthesis gel and change its composition; also, some components of the support can diffuse into the zeolite layer during calcination step at high temperature [7], and finally, the support imposes spatial constraints on crystal growth and adds a restriction to the nutrients diffusion due to its porosity and tortuosity and because, in some cases, the flux of strong adsorbing compounds can be decreased greatly by the support [8]. Therefore, synthesis inside the support pores may take place with a composition different from that of the bulk liquid.

Different supports are used, (see Section 10.6.4) with different geometry (discs or tubes), thickness, porosity, tortuosity, composition (alumina, stainless steel, silicon carbide, mullite, zirconia, titania, etc.), and symmetry or asymmetry in its structure. Tubular supports are preferable compared to flat supports because they are easier to scale-up (implemented as multichannel modules). However, in laboratory-scale synthesis, it is usually found that making good quality zeolite membranes on a tubular support is more difficult than on a porous plate. One obvious reason is the fact that the area is usually smaller in flat supports, which decreases the likelihood of defects. In Figure 10.1, two commercial tubular supports, one made of  $\alpha$ -alumina (left side) and the other of stainless steel (right side) used in zeolite membrane synthesis, are shown. Both ends of the  $\alpha$ -alumina support are glazed and both ends of the stainless steel support are welded with nonporous stainless steel to assure a correct sealing in the membrane module and prevent gas bypass.

Ramsay and Kallus [9], as well as other authors [10,11] pointed out that the distribution of the zeolite within the support, i.e., the zeolite preferentially deposited inside the porous structure of the support or the zeolite material as a thin layer on top of

**FIGURE 10.1** Commercial  $\alpha$ -alumina and stainless steel supports.

the porous support, apart from influencing its mechanical strength and defect properties of the membrane, may also cause differences in gas separation behavior.

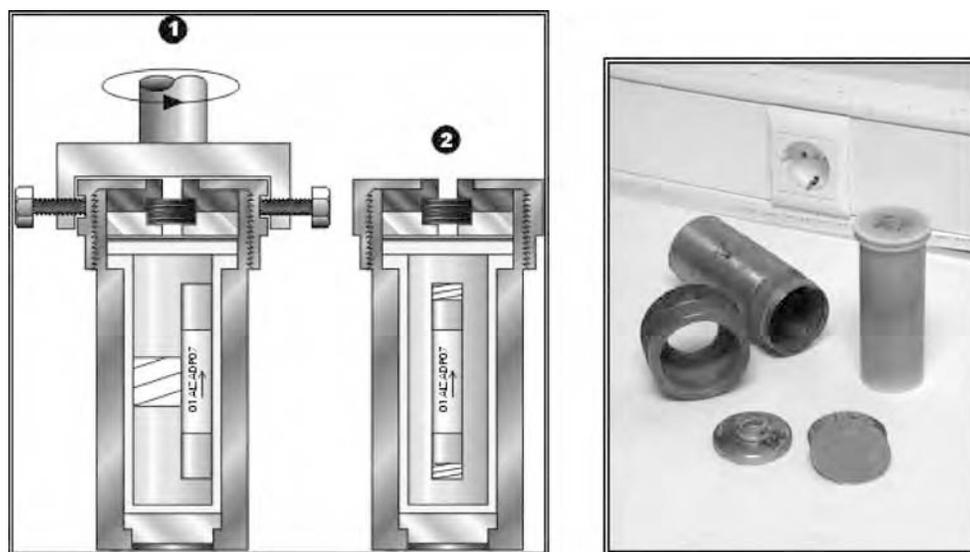

Supported zeolite membranes have been prepared using numerous procedures [4] such as alignment of crystals in electrical fields, electroplating, self-assembly, growth on organic molecular layers, covalent linkages, hydrothermal synthesis (in situ and ex situ), hydrothermal method microwave heating assisted, dry gel method (vapor-phase transport method and steam-assisted crystallization), synthesis at the interface between two fluid phases, etc.

Typically, a zeolite membrane is synthesized by heating in an autoclave under autogenous pressure, an alkaline reaction mixture containing the silica or aluminum sources, water, and in some cases, a template or organic additive (structure-directing agent) and optionally, a metal ion. The replacement of  $\text{OH}^-$  for  $\text{F}^-$  as a mineralizer agent makes possible to obtain zeolites at low pH values, and increases the organophilic character of the resulting zeolite membrane. Most of the synthesis gels have a template in their composition; however, it is necessary to remove this structure-directing agent after synthesis to render the microporous framework. The template is trapped within the growing zeolite framework. An oxidation procedure at a high temperature is the most common method used for template removal from zeolites. Though, due to the different expansion thermal coefficient of zeolites and supports and due to the changes in lattice parameters of the zeolite crystals as a result of the removal, cracks and pinholes appear after calcination. Different techniques have been used to minimize that inconvenience such as synthesis without template, calcination with slow heating and cooling rates (there is controversy in this aspect [12]), calcination at low temperatures in ozone atmosphere [13], UV irradiation with ozone [14], removal of the template by means of extraction [15], and so on.

During the hydrothermal synthesis, different variables affect the quality and purity of the resulting membrane, such as support influence (porosity, composition, structural symmetry, roughness, etc.), chemical gel composition of the precursor gel (ratio Si/OH, ratio Si/Al, Si/cation, Si/template, pH of the solution, etc.), ratio volume precursor gel/autoclave volume, synthesis time, synthesis temperature, aging of the precursor synthesis gel, heating procedure (convection, microwave, etc.), and contact configuration between the support and the precursor gel (static, rotatory, centrifuge, semi-continuous, etc.). In Figure 10.2 (right side) a commercial Parr autoclave used in membrane synthesis is shown. In Figure 10.2 (left side), there are shown two possible placements of the supports and the synthesis gel inside the autoclaves used in membrane synthesis. In the setup 1, shown on the left side, the synthesis takes place under continuous rotation to avoid gravitational crystallization effects and to achieve a more homogeneous deposition. The entire autoclave vessel is filled with the synthesis gel, and the membrane is formed on both sides of the support. In setup 2, the synthesis is static and only the inner part of the support is filled with the synthesis gel, hence, the layer is formed in the inner part of the tube. For the same precursor gel and hydrothermal synthesis conditions, each placement renders membranes with different zeolite material distribution and separation behavior [11].

To assess about the quality and purity of the synthesized membranes, several experimental techniques and procedures are available; many of those are commonly employed in catalyst characterization. Thus, XRD (x-ray diffraction) analysis of the supported samples is conventionally used to identify the type of zeolite, the proportion of amorphous material and impurities, and the preferential orientation of the crystals (XRD-pole figure). However, for the vast majority of the synthesis procedures described, the XRD spectra of the scrapped membrane or the resulting powder from the liquid phase is supplied to avoid the support contribution.

Figure 10.3a and 10.3b shows, respectively, the XRD spectra of a supported NaA zeolite membrane and of the resulting powder after filtering and drying of the liquid phase. Scanning electron microscopy (SEM) observations allow the evaluation of membrane thicknesses, shape, and size of the crystals, homogeneity and uniformity of the zeolite layer, and a first impression on the existence of intercrystalline defects. SEM-EDX (energy-dispersive x-ray analysis) can be used to measure qualitatively and quantitatively the atomic compositions of the zeolite membrane at different axial and longitudinal positions to check the

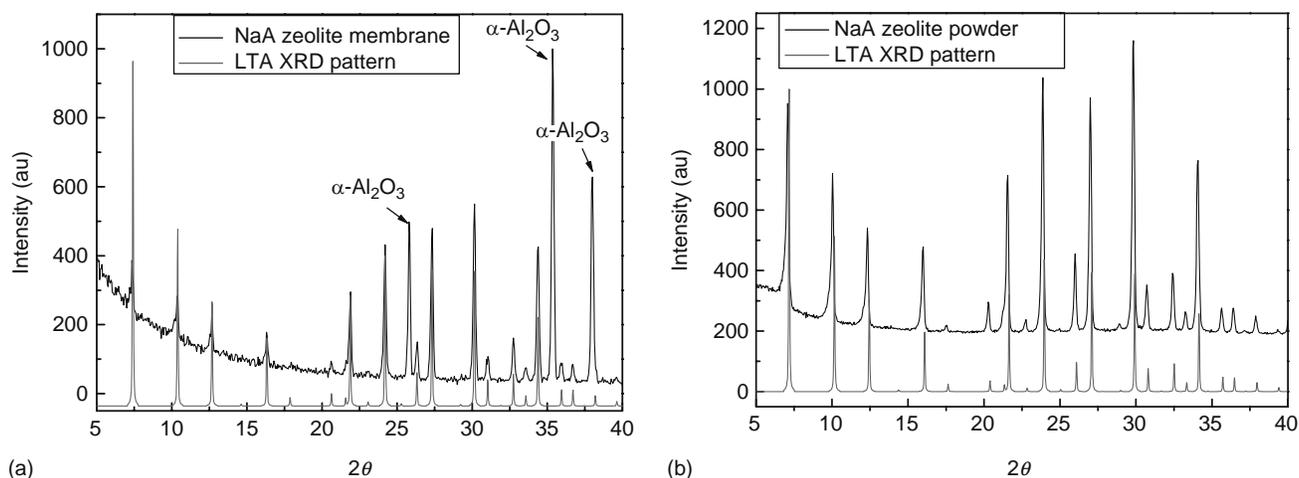

**FIGURE 10.2** Left: two different contact configurations between the support and the synthesis gel during hydrothermal synthesis. Right: Commercial autoclave from Parr Instrument Company (<http://www.parrinst.com/>).

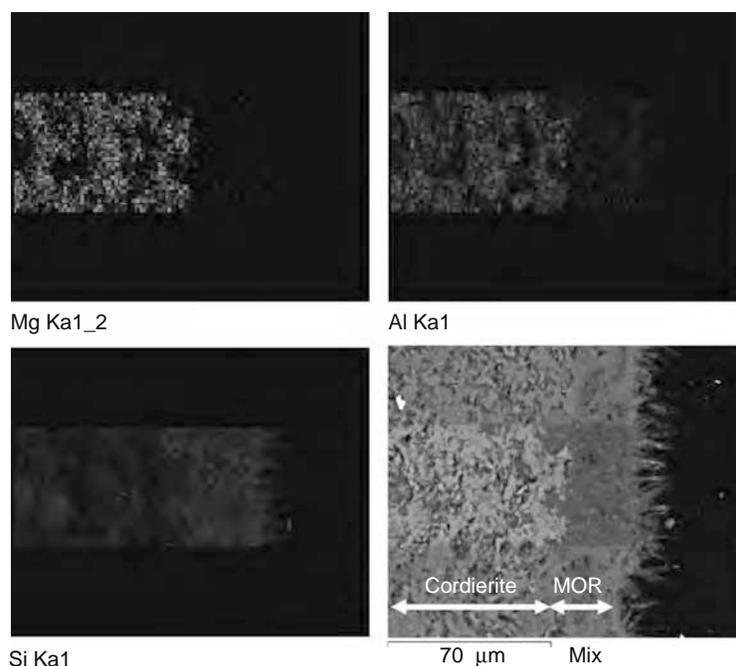

continuity and thickness of the zeolite coating. Figure 10.4 shows the EDX mapping of the cross section of a cordierite ( $\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$ ) monolith coated with a mordenite layer ( $\text{Si}/\text{Al} = 10$ ). The different colors are related to the atomic distribution across the sample. The matching between Mg, green colored, inherent to the cordierite, and Si, blue colored, in which MOR is enriched, enables us to distinguish the zeolite distribution. At the same time, it can also be observed that traces of Mg are incorporated in the zeolite layer and to ascertain the penetration of the zeolitic material into the macroporous cordierite support.

XPS (*x*-ray photoelectron spectroscopy) utilizes photoionization and energy-disperse analysis of the emitted photoelectrons to study the composition and electronic state of a region of the surface of a zeolite. However, all these techniques are destructive ones, and for that reason other methods such as isotopic-transient experiments or reflectance [16] and fluorescence [17] imaging can be used to estimate the effective membrane thickness.

The lack of methods for a fast and reliable assessment of membrane quality is still one of the outstanding issues in zeolite membrane development. The usual meaning of the term “quality” relates to the ability of the membrane to carry out a given separation, therefore, is a system-specific property and the universal membrane quality test does not exist. In general, specific permeation measurements at different temperatures, either of single gases (or vapors) or of multicomponent mixtures in the gas or liquid (pervaporation) phase, provide extremely useful information on the effective pore structure of the membrane, on the

**FIGURE 10.3** (a) XRD spectra of an inner zeolite NaA membrane on  $\alpha$ -alumina support and (b) XRD spectra of the corresponding dry powder collected in the synthesis autoclave.

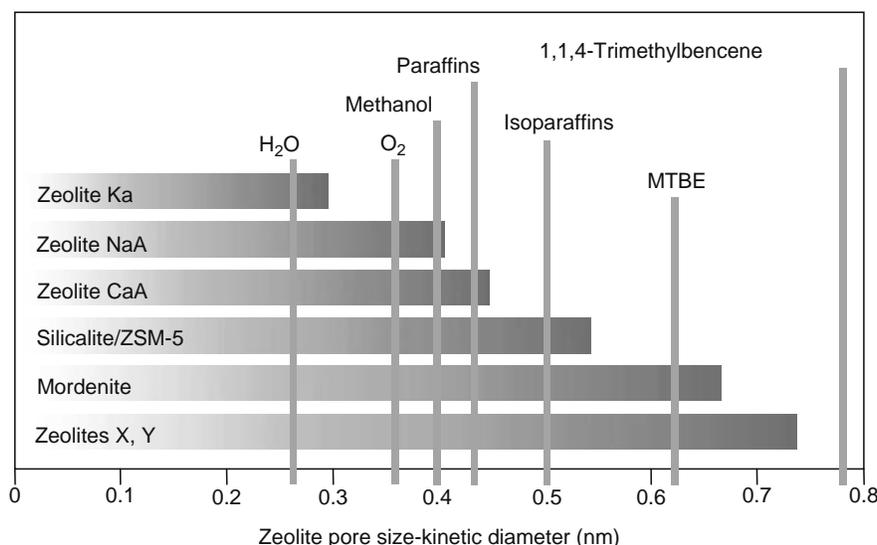

**FIGURE 10.4** (See color insert following page 588.) EDX mapping of the cross section of a cordierite ( $\text{Mg}_2\text{Al}_4\text{Si}_5\text{O}_{18}$ ) monolith coated with a mordenite layer ( $\text{Si}/\text{Al} = 10$ ).

existence of intercrystalline defects, and amorphous material, as well as information about the main transport controlling effect (adsorption or diffusion).

A battery of single-gas permeation experiments using molecules with different kinetic diameters could be used to gauge the effective pore size in defect-free membranes (see Figure 10.5). Usually, the kinetic diameter of the gases is calculated using the critical diameters or the Lennard-Jones kinetic gas theory, and the sizes of the zeolite channel are calculated using XRD data. However, as mentioned earlier, it is important to point out that molecules larger than the zeolite channel windows can absorb and diffuse to some extent, especially at high temperatures, because the zeolite framework is not a rigid structure.

Alternatively, selective blocking of membrane pores by condensing vapors combined with permeation measurements (permporometry) could be used to evaluate defects [18]. However, this method gives only pore sizes and does not consider other specific interactions between the membrane and the permeating molecules. Bernal et al. [19] have developed a fast and simple technique to assess membrane quality taking into account the nature (organophilic vs. hydrophilic) of the zeolite

**FIGURE 10.5** Molecules admitted to zeolites according to molecular dimensions and zeolite aperture sizes.

and selecting adsorbate molecules accordingly. The working hypothesis is that specific interactions can be measured by the reduction in flux after exposing the membrane to an appropriate adsorbate or by the time required to reach steady state after exposure of the membrane to quasi-saturation conditions.

Permeation experiments are often complemented by adsorption measurements, which can help to explain the permeation mechanism observed. To this end, temperature-programmed adsorption/desorption experiments are employed, based on weight measurements (thermobalance), or on continuous gas analysis. It is important to ensure that the initial state of the membrane in adsorption experiments is reproducible, i.e., there is no unwanted material previously adsorbed on the membrane.

### 10.2.1 SYNTHESIS METHODS

A survey of recent literature on zeolite membrane preparation reveals that synthesis processes, even for well-known zeolite structures (i.e., MFI, LTA), are still carried out batchwise, using a hydrothermal route to produce a thin layer from hydrogels or sols containing the corresponding nutrients. As a general rule, the reactant mixture in contact with the support changes in composition with time provoking a reduction of the membrane quality.

The so-called dry gel method [20–22] is another alternative for membrane synthesis where vapors containing templates (i.e., amines) and water are employed to crystallize silica or silica–alumina layers previously deposited onto the support (vapor-phase transport method) or where steam is used to crystallize silica and template or silica–alumina and template dry layers previously deposited onto the support (steam-assisted crystallization). Using this approach, the reactant consumption is clearly diminished, an important issue for scale-up purposes; on the other hand, synthesis time is delayed due to transport-controlled phenomena.

Basically, the hydrothermal synthesis procedures used to prepare zeolite membranes can be classified in two general groups: ex situ and in situ methods, that is with and without a previous seeding step, which are briefly discussed below.

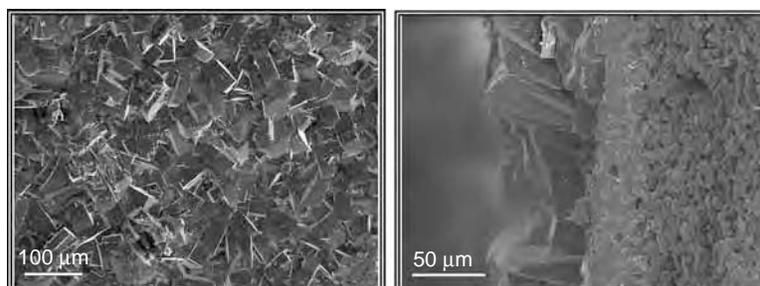

#### 10.2.1.1 In Situ Hydrothermal Synthesis Methods

Successful membrane formation in one-step (direct membrane synthesis) requires nucleation and growth of zeolite crystals on the support surface, a process that competes with solution events. Essentially, the as-received porous support is immersed in the liquid precursor gel, and the membrane is heated under autogenous pressure. Using this approach, the crystals grow in all directions, resulting membranes with random orientation in their crystals. However, it is possible, but not common, to obtain oriented membranes using in situ crystallization controlling the temperature, time, and the chemical nature and surface roughness of the substrate. As an example, Wang et al. [23] obtained *b*-oriented MFI zeolite membranes by in situ crystallization.

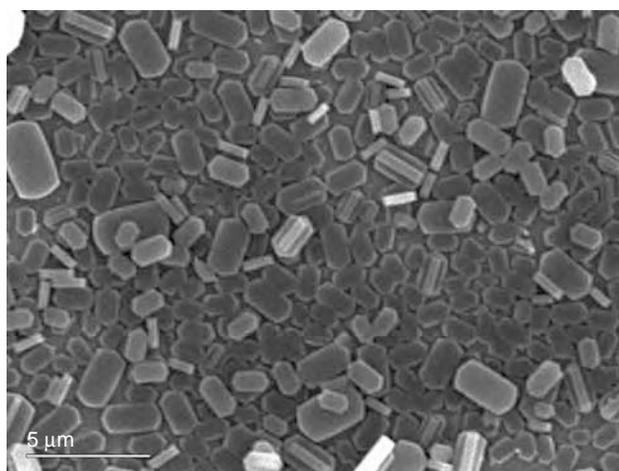

In situ crystallization shows three disadvantages, first, homogeneous nucleation cannot be avoided within the synthesis gel, second, the obtained membranes show random orientation in their crystals, and therefore, low permeances, and third, an excess of components is used during the synthesis. The great advantages of this synthesis procedure are its simplicity and that it is easy to suppress the defects by growing a thicker zeolite layer, where each new layer of crystals covers the defects in the previous layer. Figure 10.6 represents an H-ZSM-5 membrane obtained using direct in situ hydrothermal synthesis. The random orientation in the crystals is clearly observed.

#### 10.2.1.2 Ex Situ Hydrothermal Synthesis or Secondary Growth Methods

The most successful approach to control membrane formation involves segregation of the processes of crystal nucleation and growth [24]. The so-called ex situ or secondary (seeded) growth methods, unlike the direct synthesis procedures just discussed, include a first step in which a closely packed layer of colloidal zeolite crystals, synthesized homogeneously, is deposited onto

**FIGURE 10.6** Scanning electron photograph of an H-ZSM-5 membrane obtained using in situ crystallization. Left: top view. Right: cross section.

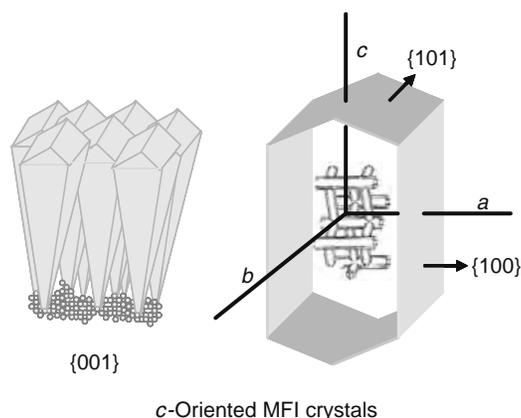

**FIGURE 10.7** Monolayer assembly of SIL-1 microcrystals on a silicon wafer by covalent linkage.

the surface of a support. These seeds act as nuclei for further crystal growth with a secondary gel under hydrothermal synthesis conditions in the second stage.

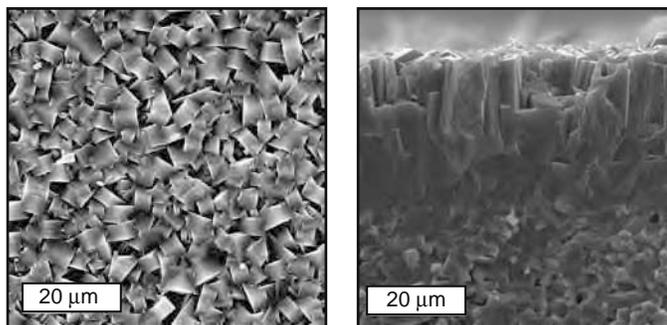

The coating or seeding methods are dip-coating, slip-casting, rubbing, spraying coating, laser ablation, spin-coating, vacuum seeding, using of electrostatic forces, and covalent linkage. The attachment and bonding properties of the crystals on support depend on the chemical potential of the support to interact or react with the approaching zeolite crystal or crystal growth front. Figure 10.7 shows the monolayer assembly of SIL-1 microcrystals on a silicon wafer by covalent linkage following the procedure described by Lee et al. [25].

Because the concentration needed for secondary growth is lower than that required for nucleation, further nucleation is strongly decreased and almost all of the crystal growth takes place over the existing crystal seeds. By controlling the composition and concentration of the secondary growth solution, the crystallization of undesired zeolite phases and the dissolution of the support can be avoided, and the rate and direction of crystal growth can, to a certain extent, be controlled.

The aim of using *ex situ* techniques is to obtain a better control of the microstructure and a preferential orientation of the crystals in the membrane with a shortened crystallization time. Preferential orientation is needed, not only for separation purposes when high fluxes are required but also for size-selective chemical sensors (see Section 10.6.6.2). Due to the anisotropy in the pore geometry of the zeolite crystals, that orientation which shows the largest channels in the direction of the flux is preferable. For example, on MFI zeolite, the straight and sinusoidal channels run parallel to the *b* and *c* axes, respectively (see Figure 10.8). The membranes prepared by secondary growth have rendered, in general, *c*-oriented membranes [24,26], i.e., sinusoidal channels perpendicular to the support surface. Figure 10.9 shows SEM images of silicalite-1 membranes on nonporous alumina support prepared by secondary growth for which *c* orientation of the crystals is clearly observed. With those zeolites, Lai et al. [27] have obtained *b*-oriented membranes where the fluxes and separation factors are very high using covalent linkages [25,28] to bond the solid crystalline seeds to the support before a secondary synthesis. MFI zeolites show their largest channels in the *b* orientation. For that reason, the membranes of Lai et al. [27] showed a superior performance in

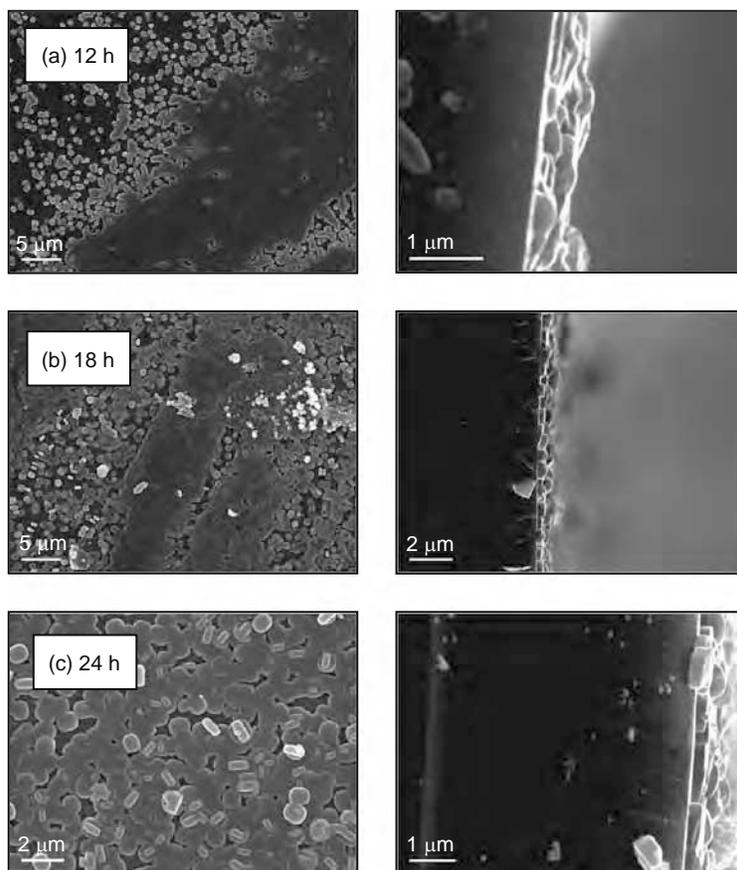

**FIGURE 10.8** (See color insert following page 588.) Schematic representation of a *c*-oriented MFI zeolite crystal.

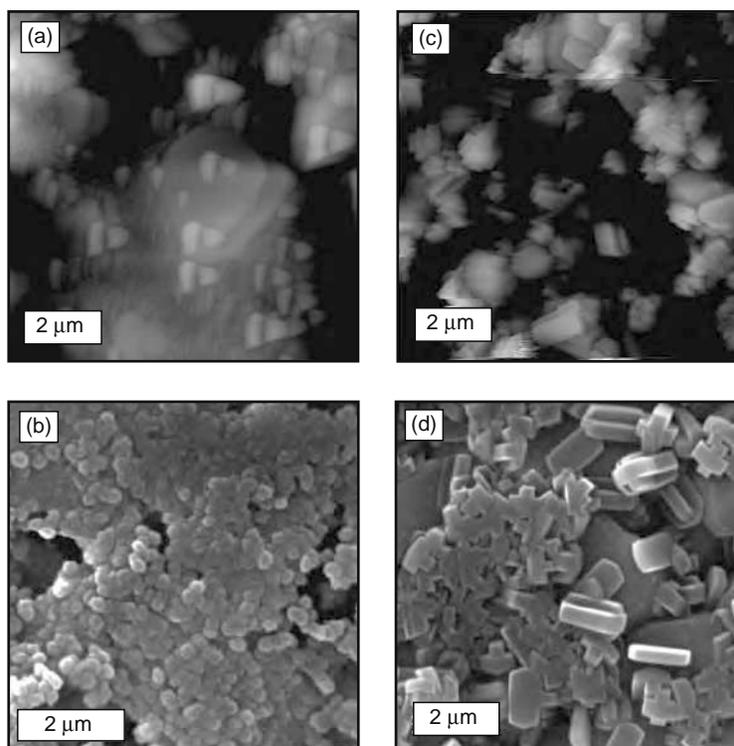

**FIGURE 10.9** Scanning electron microscopy (SEM) analysis of silicalite membranes over nonporous alumina substrates after 20 h of secondary growth synthesis conditions. Left: top view. Right: cross section.

gas separation. In Figure 10.10, top and cross-sectional views of *b*-oriented silicalite-1 layers over silicon wafers are analyzed as a function of synthesis time.

The ability of AFM (atomic force microscopy) to image the surface of nonconducting materials allows the three-dimensional observation of nanometer-size events on the zeolites at a resolution previously unattainable [29]. The complications that can arise have to do with the great surface reactivity of these materials, degrading the image quality. This technique is particularly useful for the study of the crystal growth mechanisms of zeolites, and it has been employed to adjust the synthesis conditions for crystal orientation control. AFM topographic and SEM images from the external surface of silicalite-1 layers over nonporous alumina substrates are shown in Figure 10.11 as a function of synthesis time. It can be observed that at 35 min, nearly secondary growth initiates because the zeolite crystals, circular in shape, correspond to the seeds morphology and size (around 200 nm). Conversely, after 50 min SIL-1 crystals, up to 1  $\mu\text{m}$  in size and mostly *b*-oriented, appear covering the external surface of the alumina substrate.

**FIGURE 10.10** A scanning electron microscopy (SEM) analysis of *b*-oriented SIL-1 layers over Si wafers (prepared by secondary growth using dip-coating as seeding technique) as a function of synthesis time.

**FIGURE 10.11** AFM topographic and scanning electron microscopy (SEM) images from the external surface of silicalite layers over seeded nonporous alumina substrates after synthesis time of (a, b) 35 min and (c, d) 50 min.

### 10.2.2 PRE- AND POSTTREATMENTS TO ENHANCE MEMBRANE QUALITY

In general, the properties and separation abilities of the resulting membranes depend on the synthesis procedure. The amount of zeolitic material, support composition, penetration and adhesion to the support, orientation of the zeolite crystals, the density and distribution of nonzeolitic pores (i.e., intercrystalline voids), crystal boundaries, and the thickness of the zeolite layer are the main variables which affect the quality of the obtained membrane.

Pretreatment processes, grafting and masking are aimed to improve the adhesion and to prevent the inclusion of the zeolitic material into the support. A grafting step is used when a specific direct interaction between the support and the zeolite seeds is not possible or the attachment opportunities are not available. Using this procedure the surface of the support is previously modified chemically to enhance the attraction between the zeolite seeds and the support. The masking techniques [30] consist of filling all the support pores with wax while leaving the surface free for deposition of the zeolite film, thus protecting the support by this temporary barrier from the synthesis mixture. The zeolite-coated supports are finally calcined to remove the wax from the support and the template molecules from the zeolite. Since the membrane thickness and the width of cracks are notably reduced by support masking, high fluxes and selectivities are obtained [30].

Posttreatment processes have been used to improve the quality of the resulting membranes, such as ion exchange (to provide catalytic properties or change them between hydrophobic and hydrophilic surfaces), liquid or vapor silylation, coke deposition, CVD (chemical vapor deposition), and ALCVD (atomic layer chemical vapor deposition). These techniques are used to reduce the intercrystalline gaps and the pore-mouth size, modify the acid properties of the modified membranes, and remove amorphous material. Some of these modifications have demonstrated very high separation selectivities for the resulting membranes; however, in many cases, they are of limited practical application due to the relatively low fluxes obtained.

### 10.2.3 INCREASING MEMBRANE AREA

Both, direct and secondary synthesis methods may be acceptable for small-scale applications (a few square centimeters of membrane area), but present significant problems of the synthesis of larger structures. Generally speaking, increasing the zeolite membrane area in industrial modules (see Section 10.6.4) involves the use of longer tubular or monolith supports, and reduction of tubular diameters to capillary dimensions to increase the membrane area per unit volume. In addition to the variations of composition with time that necessarily take place during batch processing, the use of longer and narrower supports will likely cause the development of concentration gradients, leading to nonhomogeneous membrane characteristics, and possibly also to the formation of defects and non-desired phases on the membrane. A number of studies have attempted to solve the problems

that prevent the synthesis of large area membranes. Up-to-date, successful membrane formation is typically achieved either by using a suitable excess of reactants or by repeated synthesis cycles. However, new attempts involving the direct heating of the substrate, while the reaction mixture is kept at lower temperature, have been demonstrated at lab-scale by Erdem-Senatarlar et al. [31,32]. In this manner, the reaction is suppressed in the bulk and promoted on the surface, and the phase transformations of metastable materials to other zeolite types thermodynamically favored can be delayed.

Even if the problems of poor crystal intergrowth due to local exhaustion of reactants in the autoclave and synthesis of zeolite material in the bulk of the solution were solved, an important problem remains, related to the fact that several batch synthesis cycles (with their associated heating and cooling processes) are often required to achieve a zeolite membrane of good quality. Thus, a synthesis procedure in which reactants are continuously supplied to the synthesis vessel while this is maintained at a constant temperature would clearly be desirable not only for performance but also for the feasibility of the scale-up. This type of approaches has already been tested for inner MFI and NaA zeolite membranes [33–35], and the results obtained indicate that the formation of concomitant phases and the amount of crystals forming in the liquid phase are greatly reduced. Similarly, the continuous seeding of tubular supports by cross-flow filtration of aqueous suspensions [36–37] has been carried out for zeolite NaA membrane preparation.

Because hydrodynamics and hydrostatics of the synthesis solution have a clear influence in the growth of zeolite films, some authors [38] have attempted to change these parameters using centrifugal forces to drive the crystal nuclei formed in the homogeneous phase toward the support before they reached a size that would be difficult to accommodate into the growing membrane, thus promoting the formation of higher quality zeolite layers.

### 10.3 NEW ZEOLITE-LIKE MICROPOROUS AND MESOPOROUS MATERIALS

In this group we include other ordered microporous structures, different from classical zeolites, containing tetrahedrally coordinated phosphorus, such as  $\text{AlPO}_4$  [39,40], SAPO-34 [41–43], and zeolite membranes containing Ti and V in their structure. These membranes, such as TS-1 [44] and VS-1 [44,45], are potentially very attractive from the catalytic applications point of view. The group of titanosilicates corresponds to framework structures made of  $\text{TiO}_6$  octahedra and  $\text{SiO}_4$  tetrahedra [45]. The ETS-4 structure with a pore size (0.3–0.4 nm) has been synthesized as a layer [46–48], the other titanosilicate with a larger pore size ( $0.49 \times 0.76 \text{ nm}^2$ ) that has been synthesized was ETS-10 [49]. The pure 5  $\mu\text{m}$  thick ETS-10 membrane exhibited a good degree of crystal intergrowth. The microporous titanosilicate ( $\text{K}_2\text{TiSi}_3\text{O}_9 \cdot \text{H}_2\text{O}$ ), with the structure of umbite and a pore size of 0.3 nm, has been reproducibly prepared for the first time as a continuous, ca. 5  $\mu\text{m}$  thick membrane on porous  $\text{TiO}_2$  tubular asymmetric supports [50]. The separation factor reported with this membrane for a  $\text{H}_2/\text{N}_2$  mixture was 48. The development of titanosilicate based membranes is likely to continue on account of some key advantages related to their preparation and properties: (1) in general, a pure phase can be obtained in the absence of costly organic templates, thus, avoiding calcination treatments, which often lead to defects or loss of active surface groups, (2) titanosilicates are usually prepared under relatively mild pH conditions, reducing the chemical attack on the support and synthesis equipment used, (3) mixed octahedral–tetrahedral oxides present novel possibilities of isomorphous framework substitution which allows the fine-tuning of the catalytic and adsorption properties of a given membrane, while preserving its microporous structure, and (4) finally, in general, these materials have a strong basicity, that provides an alternative to the acid properties of classic zeolites and opens up new application possibilities [5].

New materials that expand the microporous region of the zeolite are also interesting. In this group it is possible to find wide pore zeolite such as ITQ-21 which is accessible through six circular 0.74 nm openings [51], and extra-large-pore materials, like the phosphate-based VPI-5 or the more stable silicas UTD-1 and CIT-5 [52] with 0.8–1.2 nm openings.

Other so-called zeolite-related materials, due to their ordered inorganic structure, are the family of mesoporous aluminosilicates MCM discovered by the Mobil group in 1992 [53], with pore size between 2 and 4 nm or materials with even bigger pore sizes such as SBA-15 and SBA-16. The first synthesis of a mesoporous layer was prepared by Yang et al. [54] who deposited a MCM-41 layer on a mica substrate. MCM-41 is a two-dimensional hexagonal-ordered material, and the pores are aligned parallel to the substrate. Some authors tried to align the pores perpendicular to the surface by applying a magnetic field [55] or a pulsed laser deposition method [56]. Another option was the synthesis of the three-dimensional cubic structure with interconnected pores, MCM-48. Nishiyama et al. [57,58] synthesized the MCM-48 structure on flat  $\alpha\text{-Al}_2\text{O}_3$  supports, obtaining high fluxes in the separation of organic mixtures. The silylation of the MCM-48 membranes using trimethylsilane and triethylsilane enhanced the hydrothermal stability and the hydrophobicity reducing the pore size from 2.4 to 1.8 nm [59].

### 10.4 GAS SEPARATION: FUNDAMENTALS AND APPLICATIONS

Zeolite membranes have the potential to selectively separate gas molecules in a mixture operating under steady state, unsteady state, or under cyclic conditions whereas fixed bed adsorbers are typically operated under transient conditions. In addition, because of the inorganic nature of zeolite membranes, they have higher mechanical strength and greater thermal and chemical stability than their polymeric counterparts. Also, their ability to operate under very different conditions (total pressure,

composition, and temperature) on both sides of the zeolite membrane is a great advantage compared to conventional adsorption on discrete zeolite crystals.

Microporous inorganic membranes have pores that can be tuned to the molecular size. This enables zeolite membranes to carry out separations (i.e., the separation of isomer compounds) that are not possible with membranes in which only Knudsen selectivity is possible. Moreover, zeolite microporous membranes can compete with traditional energy costly separation methods, such as distillation of mixtures of close boiling point components, separation of mixtures of low concentration, and azeotropic distillation.

If some molecules in a mixture are too large to enter the pores of the membrane, separation can be obtained by molecular sieving. However, there is a certain degree of flexibility in the molecules and also in the zeolite pores that must be taken into account because the zeolite framework is not a rigid structure [60]. If all the components permeate through the membrane, the separation can be obtained due to differences in polarities of components, adsorption coverages, diffusion rates, and in some circumstances, the ability of one component in the feed to hinder or inhibit others from entering the pores [2]. The permeation flux of a component in a mixture is determined by the adsorption and diffusion characteristics of all the components in that mixture and also the coupling between the diffusing species [61].

### 10.4.1 SEPARATION MECHANISMS

The transport mechanisms through zeolite membranes depend on different variables such as operation conditions (especially temperature and pressure), membrane pore size distribution, characteristics of the pore surface of the zeolitic-channel network (hydrophilicity/hydrophobicity ratio), as well as the characteristics of the crystal boundaries and the characteristics of the permeating molecules (kinetic diameter, molecular weight, vapor pressure, heat of adsorption), and their interactions in the mixture.

Ideally, the zeolite membranes must be continuous with good cross-linking between crystals and free of pinholes and cracks to get high selectivities. However, most of the synthesis procedures render membranes with some intercrystalline gaps and defects. The amount of these membranes and their sizes play an important role in the overall quality of the membrane. Therefore, it has been considered illustrative to explain briefly the transport regimes in porous materials whatever the pore size, after which the mass transport mechanisms through microporous media will be fully described.

Figure 10.12 shows conceptual schemes for the different mechanisms from the nonselective (lower part of the figure) to the most selective one (upper part of the figure). It is important to note that the solution-diffusion mechanism is shown for comparison in the top of the figure, to describe the transport through polymeric membranes. In the bottom part, the nonselective transport through macro- and mesopores due to viscous flow or Poiseuille is shown. Under such regime, there is no possibility of molecular separation. It represents the molecular diffusion, characterized by elastic collisions between molecules, which prevail over molecule-wall collisions. When Knudsen diffusion takes place, i.e., in mesopores, there is possibility of separation. It occurs when the mean free path of the molecules is much larger than the pore radius of the porous media. There are more collisions between the molecules with the pore walls than with other molecules. For a binary mixture, the separation selectivity is expressed as the square root of the molecular weights of the two components. Capillary condensation takes place in mesopores when a condensable vapor is present. This vapor is able to liquefy in the pores even when the saturation partial pressure is not reached,

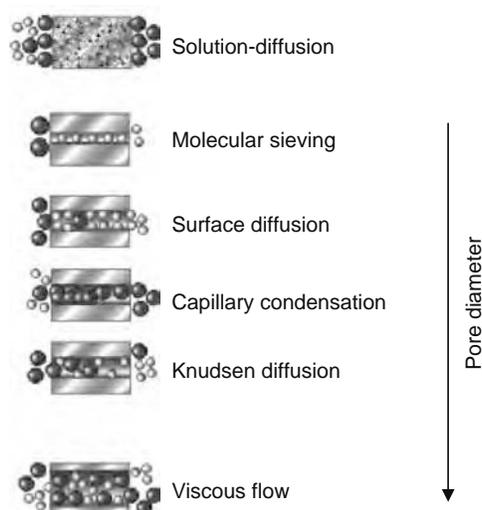

FIGURE 10.12 (See color insert following page 588.) Transport mechanisms in porous materials.

and eventually blocking the permeation of the permanent gases. It is also called liquid diffusion. Surface diffusion takes place in micro- and mesopores when the molecules adsorb on the pore walls and migrate along their surface. The effectiveness of surface diffusion depends on the product of adsorption and mobility of the permeating compounds. Under multilayer diffusion the permeabilities of condensable gases may exceed the permeability for pure gas-phase diffusion. Finally, molecular sieving through micropores represents the exclusion of molecules that are too large to enter the pores.

#### 10.4.1.1 Permeation of Individual Gases

The individual gas permeance that is experimentally measured for a zeolite membrane can be explained as the sum of two phenomena in parallel: the permeation through defects and the permeation through the zeolitic channels. If the diameter of the molecules is larger than the zeolitic channels, the permeation will clearly take place through the existing defects. This permeation can be Knudsen (mesoporous defects) or viscous (macroporous defects), although the balance between both types also depends on the operating pressure and temperature. The permeation through defects can be very substantial for molecules that are weakly or not at all adsorbed on the zeolite. In addition, capillary condensation might occur on mesoporous defects and, therefore, affecting the separation performance of the membrane.

The second contribution, i.e., permeation through the microporous zeolitic-channel network, can be due to activated gaseous diffusion or surface diffusion of adsorbed species. As a general rule, the smaller the pores size the greater the interaction of the adsorbed molecule with the pore walls.

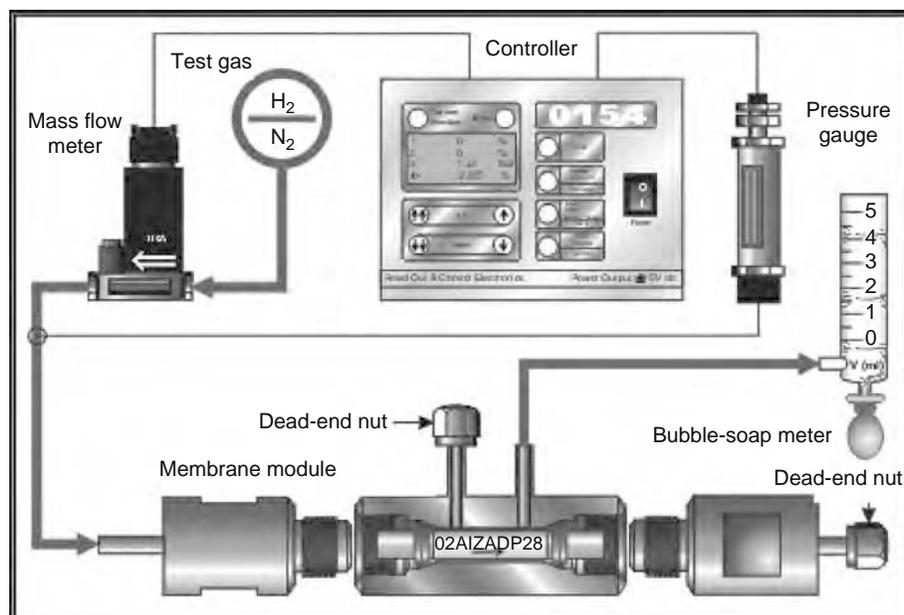

Single-gas permeation of different gases on zeolite membranes is frequently used to estimate the molecular sieving ability of a given membrane. From the absence of a clear cutoff it is possible to conclude that the mass transport is not controlled by the zeolite-pore system.

Generally speaking, the single-gas flux through supported zeolite membranes, for a given temperature, depends on the sorption capacity of the gas on the zeolite pores and its equilibrium adsorption constant (Langmuir isotherm is often used to describe the relationship between the amount adsorbed and the gas-phase pressure), the gas diffusion coefficient, the thickness of the zeolite layer, the porosity of the support, and the pressure at the feed and permeate sides.

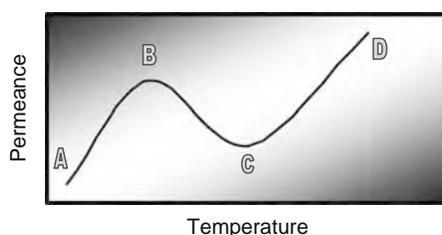

Figure 10.13 shows the experimental setup typically used for measuring the single-gas permeances of different gases on tubular zeolite membranes. When measuring single-gas permeances, the membranes are commonly sealed in a stainless steel dead-end module using silicone, Teflon or graphite *o*-rings, and a pressure drop from feed to permeate side is set.

##### 10.4.1.1.1 Qualitative Model of Single-Gas Transport through Microporous Materials

Barrer proposed a qualitative model of single-gas transport through microporous materials [62]. A five-step model can qualitatively describe the transport through a microporous membrane at moderate temperatures (see Figure 10.14):

**FIGURE 10.13** (See color insert following page 588.) Experimental system for the calculation of single-gas permeances on zeolite tubular membranes.

**FIGURE 10.14** Qualitative diagram showing the dependence of single-gas permeance with temperature.

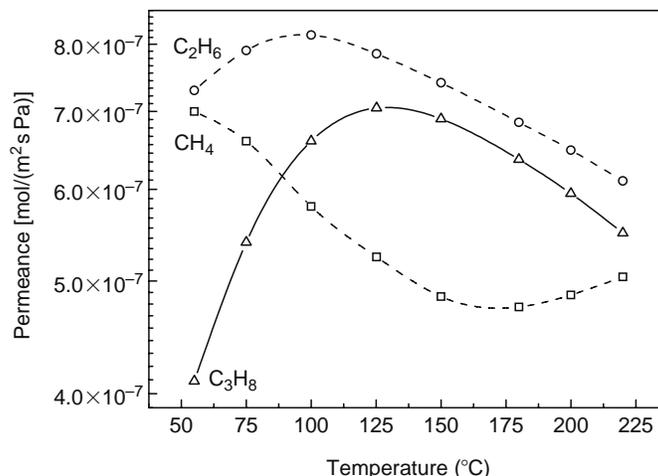

1. Transport from the gas phase to the micropore, which can take place by two parallel streams:
  - (a) Direct entrance in the micropore from the gas phase.
  - (b) Via the external surface. First adsorption of the molecules on the external surface followed by diffusion to the entrance of the micropore across the external surface.
2. Migration in the micropore.
3. Transport from the micropore to the gas phase, which can take place by two parallel streams:
  - (a) Direct exit to the gas phase from the zeolite pore.
  - (b) Via the external surface. First exit from the micropore to the external surface and then desorption of the molecules to the gas phase.

The third step, migration inside the micropore, is also denoted as intracrystalline zeolite diffusion or configurational diffusion.

The relative importance of surface diffusion and activated gaseous diffusion depends strongly on temperature [63–65] because adsorption and diffusion phenomena are molecular processes of opposite temperature dependency. Figure 10.14 is a simplified diagram showing the evolution of permeance as a function of temperature [64].

Initially, ( $A \Rightarrow B$ ), the permeance increases because the increase in temperature enhances the mobility of adsorbed species, even though the amount of physically adsorbed material starts to decrease. Eventually, point B is reached, and from this temperature, the decline in occupancy prevails which gives rise to a decrease in permeance ( $B \Rightarrow C$ ). At a sufficiently high temperature (C) the effect of adsorption becomes negligible, and the permeance is controlled by activated transport (Knudsen-like) through micropores, increasing with temperature ( $C \Rightarrow D$ ) [2]. This transport in the gaseous regime is activated, mainly due to the structural constraints of the lattice upon passage [66]. The total flux through the membrane is then the sum of the surface diffusion and the gaseous diffusion.

As an example, Figure 10.15 compiles the permeance evolution with temperature for single hydrocarbons (from  $C_1$  to  $C_3$ ) over silicalite-1 membranes supported on stainless steel tubes. A specific interaction with linear hydrocarbons appears, as it could be expected due to the organophilic character of SIL-1 membranes. For methane, the temperature used is too high to find

**FIGURE 10.15** Hydrocarbon permeances as a function of temperature for Na-ZSM-5 membranes supported on stainless steel tubes.

a maximum; but in general, the heavier the adsorbate, the stronger the adsorption and coverage degrees. This tendency is in accordance with the temperature-programmed permeance profiles and the point B temperatures (Figure 10.14), which indeed, shift toward higher values with the hydrocarbon chain length (from 100°C for ethane to 130°C for propane). The sequence shown for the permeance maxima is the same as in previous works [64–65], although the individual temperatures slightly change.

#### 10.4.1.1.2 Quantitative Model of Single-Gas Transport through Microporous Materials

Usually the transport of gases is described by Fick's first law:

$$J = -D_F(q) \frac{\delta\mu}{\delta x}$$

where  $D_F(q)$  is the Fickian diffusion constant ( $\text{m}^2/\text{s}$ ) also called transport diffusivity,  $\delta\mu/\delta x$  is the chemical potential gradient, i.e., the driving force for mass transport and might be expressed in terms of the fractional occupancy. The Fickian diffusion coefficient is assumed to be independent of coverage degree.

There are macroscopic (uptake measurements, liquid chromatography, isotopic-transient experiments, and frequency response techniques), and microscopic techniques (nuclear magnetic resonance, NMR and quasielastic neutron spectrometry, QENS) to measure the gas diffusivities through zeolites. The macroscopic methods are characterized by the fact that diffusion occurs as the result of an applied concentration gradient; on the other hand, the microscopic methods render self-diffusion of gases in the absence of a concentration gradient [67].

Conversely, the correct approach to formulate the diffusion of a single component in a zeolite membrane is to use the Maxwell–Stefan (M–S) framework for diffusion in a nonideal binary fluid mixture made up of species 1 and 2; where 1 and 2 stands for the gas and the zeolitic material, respectively. In the M–S theory it is recognized that to effect relative motions between the species 1 and 2 in a fluid mixture, a force must be exerted on each species. This driving force is the chemical potential gradient, determined at constant temperature and pressure conditions [68]. The M–S diffusivity depends on coverage and fugacity, and, therefore, is referred to as the corrected diffusivity because the coefficient is corrected by a thermodynamic correction factor, which can be determined from the sorption isotherm.

#### 10.4.1.2 Multicomponent Permeation

The permeation of mixtures is a more complex phenomenon, and in general, the behavior that is experimentally observed for mixtures cannot be predicted solely from the permeance of the individual components [5]. As will be shown below, it is often the case that in a binary mixture, the component which permeates faster as a single gas (in general the more weakly adsorbed component) is the one giving the lower permeance in the binary mixture.

Although Knudsen diffusion, shape selectivity, and molecular sieving play an important role in the separation of mixtures, the mechanisms which control the majority of the multicomponent separations in zeolite membranes are surface diffusion, and sometimes, capillary condensation. In addition, molecular simulations and modeling of M–S diffusion in zeolites [69,70] show that the slower moving molecules are also sped up in some mixtures [71,72] in the presence of fast-diffusing molecules and other times, slower molecules inhibit diffusion of faster molecules because molecules have difficulty passing one another in zeolite pores [73].

Four groups with different separation-controlling mechanisms can be distinguished: (1) separation of mixtures of non-adsorbing compounds, (2) mixtures of adsorbing organic compounds, (3) permanent gas from vapors, and (4) water or polar molecules from organic compounds.

##### 1. Separation of Mixtures of Nonadsorbing Compounds

In the ideal molecular sieving regime the interaction of the permeating species with the zeolite is minimal, and the separation takes place simply because the size and shape of some of the molecules prevent them from entering the membrane pores or move across them with substantial velocity [2]. In that regime adsorption does not play an important role, and, therefore, separation selectivity (ratio of permeances between species in the mixture) should coincide with ideal selectivity (ratio of single-gas permeances).

##### 2. Separation of Mixtures of Adsorbable Organic Compounds

When all the components in the mixture adsorb onto the zeolite-adsorption sites, the separation can be explained in terms of competitive adsorption between the permeating compounds. In the mixture, the molecules compete for those adsorption sites, and at high coverage degrees, this adsorption depends on the ratio of feed fugacities [74], heats of adsorption, and molecular sizes.

### 3. Separation of Permanent Gas from Vapors

In these mixtures, the vapor or organic compound can either adsorb preferentially on the zeolite pores or undergo capillary condensation in pores of small diameter, therefore blocking the membrane for the other components in the mixture (i.e., permanent gas). The separation selectivity toward the blocking molecule decreases with temperature due to the decrease in adsorption and capillary condensation.

### 4. Separation of Water or Polar Molecules from Organic Compounds

These separations are usually carried out by pervaporation (see Section 10.5) or vapor permeation but they have also been performed using gas-phase feeds on organophilic [75] or hydrophilic membranes [76]. On organophilic membranes the permeation of the organic or less polar compound is favored, while the opposite trend is expected for hydrophilic membranes.

The M–S approach allows the prediction of the mixture diffusion based on the pure component M–S diffusivities, along with the mixture isotherms (i.e., estimated using the ideal adsorbed solution theory [IAST] of Myers and Prausnitz) [68]. Experimentally, the NMR pulse field gradient technique has been used to calculate the mixture diffusion coefficients.

Two experimental setups have been used to calculate transient and steady-state permeation of different gases through zeolite membranes: the Wicke–Kallenbach method [77] and the pressure-drop method. Using the Wicke–Kallenbach method, an inert gas sweeps the permeate side to facilitate the desorption of all the adsorbed compounds and the membrane surface always faces the feed gas. In this way, concentration gradients and an absolute pressure drop can be imposed independently. The major disadvantages are that the counter diffusion of the inert sweep gas can affect the permeation of the feed components and the cost of using a sweep gas reduces its possibilities for industrial applications. Using the pressure-drop method, a pressure gradient is kept in both sides of the membrane; hence, the flux through the membrane is the real one. However, if the membrane has defects, the absolute pressure drop across the membrane might give a considerable contribution of viscous flow to the overall permeation.

## 10.4.2 APPLICATIONS

The actual membrane market for gas separation is being led by polymeric membranes; during the past 20 years, sales of membrane–gas separation equipment have grown to become a \$150 million/year business [78]. However, the future of membrane technology will be in refining, petrochemical, and natural gas industries. Larger opportunities exist for membranes in all these industries, and despite past failures, the acceptance of membrane technology is increasing. These markets will require more robust membranes and modules than those used today due to high-partial pressures of hydrocarbons and the presence of other plasticizing gases are often involved. Currently, several industrial manufacturers prepare a wide variety of organic and inorganic membranes (glass, silica, titania, zirconia, metallic, ceramic, and carbon) [79]. However, commercial applications of zeolite membranes have only been developed for pervaporation and vapor permeation processes. For gas separations, zeolite membranes are still only used on the laboratory scale. The major restriction to the industrial development of zeolite membranes is their high cost. In fact, large-scale separations are unlikely to be implemented industrially unless the price of zeolite membranes undergoes a reduction by a factor of 10 [80].

This cost differential can be tolerated only in applications in which polymeric membranes completely fail in the separation [78]. Demanding separation applications, where zeolite membranes could be justified, due to the high temperatures involved or the added value of the components, and have been tested at laboratory scale, are the following: separation of isomers (i.e., butane isomers, xylene isomers), organic vapor separations, carbon dioxide from methane, LNG (liquefied natural gas) removal, olefines/paraffins and H<sub>2</sub> from mixtures. In most cases, the separation is based on selective diffusion, selective adsorption, pore-blocking effects, molecular sieving, or combinations thereof. The performance or efficiency of a membrane in a mixture is determined by two parameters: the separation selectivity and the permeation flux through the membrane.

In general, when carrying out a new separation, the kinetic diameter and the heat of adsorption of the gases, which compose the mixture, are the main variables used to select the most adequate zeolite. MFI, FAU, LTA, SOD, ANA, DDR, MOR, BEA, CHA, FER, KFI are zeolite structures widely used as membranes for different separations. In gas separation, MFI zeolite membranes (silicalite-1, ZSM-5, and with Al, Fe, B, and Ge isomorphously substituted into their structures) are the most commonly used membranes because their pores (~0.55 nm diameter) are in the size range of many industrial mixtures; furthermore, their synthetic chemistry is well established in the literature.

Table 10.1 summarizes recent results concerning gas separations; for an exhaustive revision up to 1999 the reader is referred to the review of Coronas and Santamaría [2].

We have divided the applications of zeolite membranes for gas separations into two main groups based on and depending on whether there is molecular exclusion or not in one of the components to be separated.

For the separations discussed in the following sections, the separation factor achieved using the same synthesis procedure and experimental setup (Wicke–Kallenbach or pressure drop) strongly depends on temperature and pressure, and to a lesser but still important extent on the orientation of the crystals in the membrane, the effective thickness of the layer, the support (nature

and resistance), the penetration of the zeolite crystals within the pores of the support, the distribution of non-zeolitic pores, and the grain boundaries.

#### 10.4.2.1 Separations Controlled by Sorption-Diffusion Mechanisms When Size Exclusion Occurs

Separation due to molecular sieving alone can only take place if the membrane is defect free and there is no adsorption of the permeating species on the zeolite crystals (i.e., at high temperatures) or the components in the mixture adsorb with similar heats of adsorption. For those mixtures, the shape and size of the components compared to the zeolite-pore sizes direct the separation toward molecular sieving. For example, the separation of H<sub>2</sub>/SF<sub>6</sub> or N<sub>2</sub>/SF<sub>6</sub> on MFI zeolite membranes at high temperatures where SF<sub>6</sub> does not adsorb significantly. In fact, the latter separation is commonly used to evaluate the membrane quality. Methane/*i*-octane represents another example of this mechanism since *i*-octane cannot fit into the MFI structure and the heat of adsorption of methane is very low in the zeolite [2].

Normally, a combination of molecular sieving and adsorption controls the separation. For separations where the adsorption starts to play an important role, it turns into the controlling separation mechanism, i.e., the separation of *n*-C<sub>6</sub>/2,2 DMB on MFI membranes [30,85]. In this case, not only the exclusion due to the size but also the slight difference in the heats of adsorption of the linear and branched alkanes in the MFI structure can result in a large difference in permeances due to the shape selectivity, because the linear alkanes are located more or less randomly in the zeolitic channels and the branched ones are preferentially adsorbed in the intersections. *n*-Hexane molecules (0.43 nm kinetic diameter) can enter the MFI pore structure and diffuse within MFI channels, whereas the diffusion of 2,2-DMB molecules should be largely restricted by size limitations (0.62 nm kinetic diameter). Although, the flux of 2,2-DMB in MFI membranes may be through defects. Hence, *n*-hexane strongly inhibits 2,2-DMB permeance and molecular sieving plays a secondary role.

Another example where molecular sieving and preferential adsorption control the separation is the separation of CO<sub>2</sub>/CH<sub>4</sub> in CHA and DDR zeolite membranes [43,81]. The separation of CO<sub>2</sub> from natural gas is important during its transport and combustion because of the acidic and corrosive character of CO<sub>2</sub> in the presence of humidity; and moreover, it reduces the methane number (similar to the octane number in gasoline) which is important for getting high efficiency during combustion.

Adsorption isotherms for CO<sub>2</sub> and CH<sub>4</sub> on SAPO-34 crystals reveal that CO<sub>2</sub> is adsorbed more strongly, and thus, preferential adsorption is partially responsible for the selective permeation of CO<sub>2</sub>. Also, SAPO-34 crystals have pores ( $0.38 \times 0.38 \text{ nm}^2$ ) similar in size to CH<sub>4</sub> (0.38 nm), and are bigger than CO<sub>2</sub> (0.34 nm); therefore, CO<sub>2</sub> diffuses faster than CH<sub>4</sub>. Li et al. [43] reported separation selectivities up to 67 with SAPO-34 membranes under conditions (room temperature) where the strongly adsorbing component, CO<sub>2</sub>, hinders methane permeance. Recently, small pore DDR membranes have been used [81] showing CO<sub>2</sub>/CH<sub>4</sub> separation factors as high as 220 at 301 K. Again, DDR membranes have pores ( $0.36 \times 0.44 \text{ nm}^2$ ) that are similar in size to CH<sub>4</sub> and therefore, a configurational impediment to the flux of methane takes place in addition to the preferential adsorption of CO<sub>2</sub>.

The separation of xylene isomers on MFI zeolite membranes can be considered one example of intracrystalline size exclusion and competitive adsorption (strongly dependent on coverage). The difference in their kinetic diameters ( $\approx 0.58 \text{ nm}$  for *p*-xylene and  $0.68 \text{ nm}$  for *o*- and *m*-xylene) indicates the possibility of an effective separation using MFI membranes (see Table 10.1). The kinetic diameter of *p*-xylene is close to one of the MFI channels ( $\approx 0.55 \text{ nm}$ ) whereas *o*- and *m*-xylene might be excluded. Therefore, MFI zeolite channels and crystal grain boundaries determinate the permeation characteristics [27].

#### 10.4.2.2 Separations Based on Competitive Adsorption without Size Exclusion

*n*-C<sub>4</sub>/*i*-C<sub>4</sub> separation on MFI membranes [10,11,21,22] is an example of competitive adsorption, and has been used as a quality-control parameter when adsorption effect is controlling, because *n*-butane strongly adsorbs on the MFI zeolite membrane even at moderate high temperatures. The separation factor *n*-C<sub>4</sub>/*i*-C<sub>4</sub> and permeances for a silicalite membrane are depicted in Figure 10.16a as a function of temperature. A maximum separation factor could be observed at around 55°C, as a result of *n*-butane adsorption and *i*-butane mobility. Figure 10.16b shows the results at different partial pressures of *n*-butane at constant temperature (25°C). As expected, higher the *n*-butane partial pressure higher the coverage degree increasing the blocking effect of *n*-butane and the separation factor.

Nevertheless, even for defective zeolite membranes (i.e., presence of cracks and pinholes), higher *n*-butane/isobutane separation factors [95] could be potentially achieved by intercrystalline adsorption and capillary condensation.

In general, if both components in the mixture strongly adsorb, the separation selectivity increases as the difference in the strength of adsorption of the permeating components increases.

The separation of CO<sub>2</sub>/CH<sub>4</sub>, which was earlier mentioned, can take place with FAU membranes [96], but in this case, only competitive adsorption controls the separation because both CO<sub>2</sub> and CH<sub>4</sub> molecules are much smaller than the FAU channel pores (0.74 nm). Similarly, the separation CO<sub>2</sub>/N<sub>2</sub> on FAU and MFI membranes ( $0.53 \times 0.56 \text{ nm}^2$  and  $0.51 \times 0.55 \text{ nm}^2$ ) [82] is mainly based on the preferential adsorption of the CO<sub>2</sub> that inhibits N<sub>2</sub> permeance. The influence of cation exchanged in FAU was extensively studied by Kusakabe et al. [83,84,97,98]. These authors found out a remarkable increase in the separation factor (from 19 to 39) when the Na-Y zeolite was ion exchanged with K, due to an improvement in the CO<sub>2</sub>/N<sub>2</sub> sorption selectivity [83]. Moreover, the influence of the ion-exchange degree of larger cations such as Rb and Cs and the subsequent washing step after was further analyzed [84]. For the incompletely washed samples, the chloride salts impregnated in the membrane seem to enhance the CO<sub>2</sub> selectivity reaching values of 149 with a CO<sub>2</sub> permeance of  $1 \times 10^{-6} \text{ mol/m}^2 \text{ s Pa}$ .

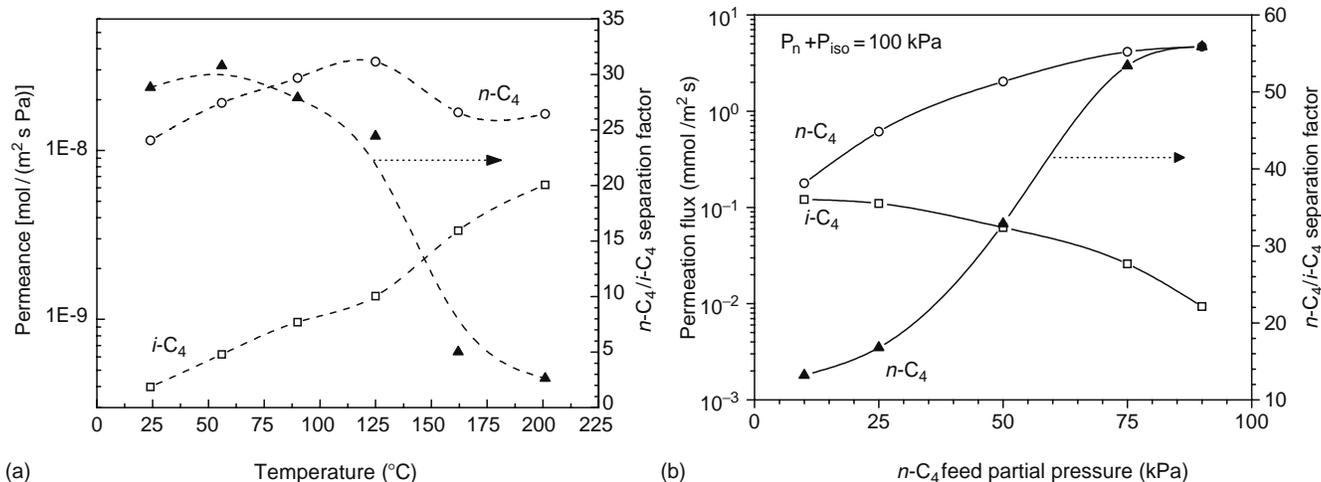

FIGURE 10.16 *n*-C<sub>4</sub>/*i*-C<sub>4</sub> separation performance of a SIL-1 membrane: as a function of (a) temperature and (b) *n*-C<sub>4</sub> feed partial pressure.

The adsorption of gases on zeolites depends on the occluded cations and on the presence of acid sites in the zeolite structure. For instance, alkenes adsorb stronger than alkanes on FAU zeolite membranes because of their higher affinity for the cations [99,100]. In a similar way, on MFI zeolites with acid sites, alkenes adsorb preferentially over alkanes for the same number of carbon atoms [101]. On the other hand, for MFI membranes without acid sites (i.e., silicalite-1) the olefin/paraffin separation principle is just the opposite because the adsorption strength decreases in the following order: alkane > alkene. However, the separation factor could be reversed as a function of the hydrocarbon relative pressure ( $P_{rel}$ ). Thus, in the Henry regime (i.e., at low  $P_{rel}$  values), there is hardly adsorption competition toward zeolite sites, and alkane coverage prevails over alkene one ruled by the adsorption constant value. Near saturation, configurational entropy effects control the separation mechanism rendering in a preferential alkene adsorption [102]. Further efforts need to be concentrated in this field because large opportunities for zeolite membranes in the separation of light hydrocarbon mixtures exist. The separation of propene/propane gas mixtures from various reactor vent streams could open up large new membrane markets. In a recent publication, Giannakopoulos et al. [103] have improved the previously reported results on propene-propane mixtures, achieving maxima values for the separation factor and ideal selectivity of 13.7 and 28 at 100°C and 35°C, respectively.

Zeolite membranes can withstand relatively high temperatures in the presence of oxygen; thus they can compete with polymeric and carbon membranes in the separation of refinery gas streams [7,88,104] and in the removal of heavy hydrocarbons from synthetic natural gas [86]. Those separations are based on competitive adsorption of hydrocarbons on the zeolite, and an increase in the concentration of any of the adsorbing species increases its surface coverage, leading to higher selectivities for that particular specie. In addition, there are some practical limitations for those separations, such as the high pressure of the natural gas in the pipeline, high temperatures in refinery gas streams, and presence of impurities [105], that make the zeolites promising candidates to achieve high selectivities and fluxes. It is worthwhile to emphasize that the capability of zeolite membranes to handle with natural gas separations opens up a remarkable potential market due to the total worldwide production of raw gas is about 50 trillion scf/year. According to the future predictions of Baker [78], over the next 10–20 years, the use of membranes for natural gas processing could easily grow up to become the largest single membrane-gas separation application.

Finally, the separation of vapors or adsorbable organic compounds from nonadsorbing permanent gases, such as alcohol/O<sub>2</sub>, alcohol/H<sub>2</sub>, *n*-C<sub>4</sub>/H<sub>2</sub>/H<sub>2</sub> on MFI membranes when the size of the organic compound does not represent size exclusion; should also be included in this group. In general, the permeance of the nonadsorbing permanent gas is blocked due to the adsorption or capillary condensation of the adsorbable compound within the zeolite channels or onto the intercrystalline defects, respectively. Separation factors as high as 520 have been obtained for an MFI zeolite membrane in the separation of *n*-C<sub>4</sub>H<sub>10</sub>/H<sub>2</sub> with an *n*-butane permeance of  $0.78 \times 10^{-8}$  mol/Pa s m<sup>2</sup> at room temperature [88]. Conversely, separations of H<sub>2</sub> from hydrocarbons on LTA zeolite membranes [93,94] and H<sub>2</sub> from N<sub>2</sub> on MFI membranes (Gavallas ZSM5) represent examples in which diffusion effects play the main role because the molecule with the smaller kinetic diameter permeates preferentially. Although for these cases competitive adsorption does not take place, the authors have considered appropriate to include them within this section to emphasize that the separation factor can be reversed (i.e., *n*-C<sub>4</sub>H<sub>10</sub>/H<sub>2</sub> vs. H<sub>2</sub>/*n*-C<sub>4</sub>H<sub>10</sub>) by choosing the adequate zeolite membrane. However, there are relative few studies found in literature concerning gas separation applications with type-A zeolite membranes ( $0.41 \times 0.41$  nm<sup>2</sup>). With tubular supports, the best results found for gas separation are 8.33 for a H<sub>2</sub>/*n*-butane equimolar mixture with a H<sub>2</sub> permeance value of  $7 \times 10^{-10}$  mol/m<sup>2</sup> s Pa at 473 K [93] and 7.97 for a H<sub>2</sub>/propane equimolar mixture with a H<sub>2</sub> permeance value of  $6.7 \times 10^{-8}$  mol/m<sup>2</sup> s Pa at 323 K [94]. Until now, no highly permselective A-type membranes have been reported; indeed, the permeation tests always revealed that those membranes contain non-zeolitic pores (defects) larger than the zeolitic pores through which large molecules (i.e., *n*-butane with a kinetic diameter of 0.43 nm) were able to diffuse, explaining the selectivities close to the Knudsen values.

Within this group of applications, it is worthwhile to include examples related with separations at trace levels. Recently, Aguado et al. [90] carried out the removal of model pollutants (*n*-hexane, formaldehyde, and benzene) present at very low concentration levels (2–230 ppmv) from indoor air using MFI zeolite membranes achieving separation factors as high as 250 for certain conditions. On the basis of this concept, a novel high-quality air-conditioning system may be envisaged as commercial domestic application for zeolite membranes.

## 10.5 PERVAPORATION

Whenever we are talking about zeolite applications, pervaporation comes to mind, since it is the first industrial application of zeolite membranes that has been successfully operating since May 1999 by Mitsui Engineering & Shipbuilding Co., Ltd. The plant was designed for a feed flow of 600 L/h and a concentration of water in the feed of 10 wt%, using 16 tubular type modules having 125 membranes of zeolite A each [106]. Also, a vapor permeation plant has been operating since September 1999 for a lens cleaning operation process, 24 double-tube type modules having a piece of zeolite membrane each [106,107].

Pervaporation is a separation process where a liquid mixture is fed to one side of the membrane; one component permeates preferentially through the membrane to the other side where it evaporates because the pressure is reduced in this side, either by vacuum or by a sweep gas. After that, the gas is condensed in a cold trap. Figure 10.17 shows a schematic diagram of

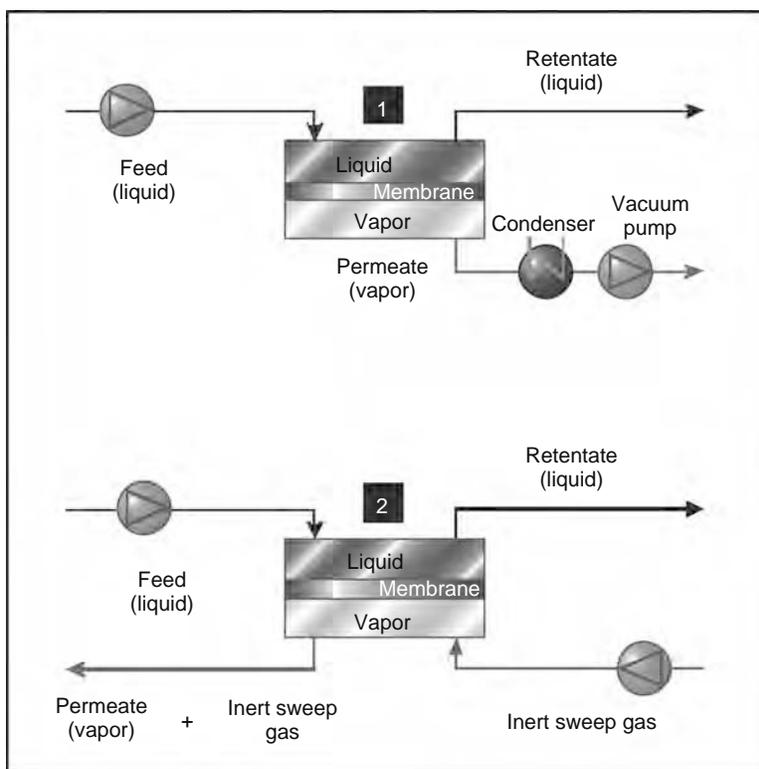

FIGURE 10.17 (See color insert following page 588.) Schematic diagram of pervaporation.

pervaporation. In vapor permeation the feed is a vapor, saturated or not, instead of a liquid. The driving force for pervaporation is the fugacity of the component that permeates through the membrane. Pervaporation occurs in three steps: (1) the liquid feed adsorbs onto the membrane, (2) there is a diffusion process through the membrane, and (3) the component desorbs into the vapor phase at the permeate side. The three steps are illustrated in Figure 10.18.

The performance of a membrane in pervaporation is based on the amount of liquid that permeates, pervaporation flux, which usually is expressed in kilogram per square meter hour, and the ability to separate the components in the mixture, which

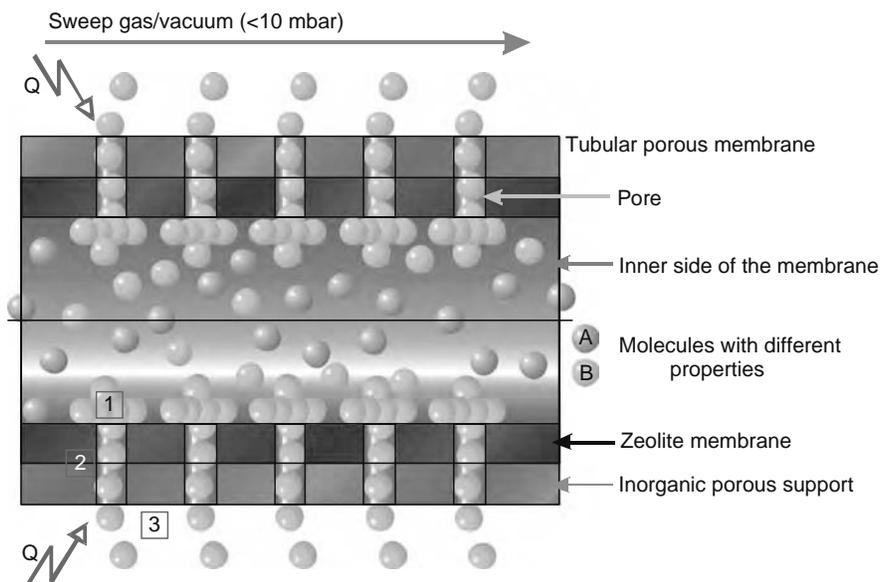

FIGURE 10.18 (See color insert following page 588.) Steps involved in pervaporation: (1) adsorption, (2) diffusion, and (3) desorption.

is given by the separation factor,  $\alpha_{i/j}$ , defined as the ratio of the weight fraction components in the permeate divided by the ratio of the weight fraction of the components in the feed.

$$\alpha_{i/j} = \frac{y_i^p / y_j^p}{x_i^f / x_j^f}$$

Distillation is a unit operation based on the relative volatility of the components in the mixture; this unit operation encounters many problems in the separation of azeotropic mixtures, close boiling point mixtures, isomer separation, and removal of thermally sensitive compounds. Azeotropic distillation is an alternative; however, it adds a third component to break the azeotrope and this solution is not environmental friendly and cost effective. Pervaporation could overcome these drawbacks and it is presented as a solution for the separation of these kinds of mixtures. In this section, we discuss the separation of different azeotropic and close boiling point mixtures.

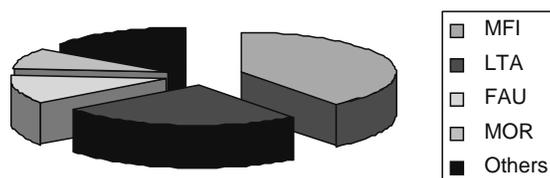

Zeolite membranes are not the only kind of membranes that have been used in pervaporation, organic and other types of inorganic membranes, different from zeolites, have been employed. Polymeric membranes of PVA (polyvinylalcohol) have been widely employed for dehydration and separation of organic mixtures; however, their main limitations are related to their low thermal and chemical stability. When the water content in the feed mixture is high, polymeric membranes suffer from swelling; moreover, in the separation of organic mixtures they usually present a low selectivity.

Since the pioneering work of Tehennepe et al. [108] in 1987 many efforts have been made filling the polymeric matrix with zeolites to improve their stability. There are several companies, such as Sulzer Chemtech, that offer pervaporation organic membranes and composite membranes [109].

The inorganic silica membranes, also commercial, have solved the problem of thermal and chemical stability; however, these membranes are only used for dehydration purposes, leaving the problem of separation of organic mixtures unsolved. As we have seen previously, due to the versatility and special features of zeolites, new applications in pervaporation that are not possible with other membranes could be developed with zeolite membranes. Gallego-Lizon et al. [110] compared different types of commercial available membranes: zeolite NaA from SMART Chemical Company Ltd., silica (PERVAP SMS) and polymeric (PERVAP 2202 and PERVAP 2510) both from Sulzer Chemtech GmbH, for the pervaporation of water/*t*-butanol mixtures. The highest water flux was obtained with the silica membrane (3.5 kg/m<sup>2</sup> h) while the zeolite membrane exhibited the highest selectivity (16,000).

The main disadvantage of zeolite membranes is their cost; there are several studies related to this subject [80,111]. Meindersma and Haan [80] studied the economical feasibility of pervaporation or vapor permeation processes for the separation of aromatic compounds from a naphtha cracker feed and modeled the separation of benzene from cyclohexane taking into account the separation data presented by Kita et al. [112], with an FAU membrane. The results indicated that the selectivity of the membranes to the aromatics should be at least 40 and preferably 80 to avoid large membrane areas. The conclusion is that the cost of the zeolite membrane, estimated at that time in 2000 £/m<sup>2</sup>, needs to be reduced by a factor of 10 to get an economically feasible application. On the other hand, the recent economic study [111] for the dehydration of isopropyl alcohol comparing azeotropic distillation with pervaporation using either zeolite commercial membrane (NaA type zeolite, Mitsui & Co.) or polymeric (PERVAP 2510, Sulzer Chemtech GmbH) estimated that a hybrid distillation system with zeolite membranes is the most interesting process from an economic point of view. The economic calculations were accompanied by experimental results of both membranes. The zeolite membrane price, including the module obtained from the supplier, was 3400 £/m<sup>2</sup> in this case.

Many publications refer to pervaporation with zeolite membranes and recently the group of Falconer and Noble has presented an excellent review paper [113] about this subject. In a bibliographic search about pervaporation and zeolites for the last 10 years we find that many efforts, 28% of the publications, pertain to composite zeolite-polymer membranes, and the rest correspond to different zeolite structures that are summarized in the pie chart shown in Figure 10.19. The most studied structure

**FIGURE 10.19** (See color insert following page 588.) Distribution of publications about zeolite membranes in pervaporation during the last 10 years. (From ISI Web of Knowledge. Web of Science.)

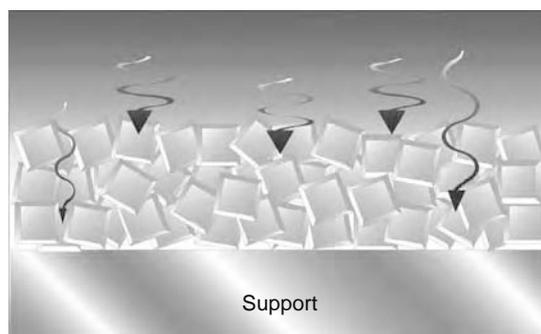

FIGURE 10.20 (See color insert following page 588.) Transport through intercrystalline and intracrystalline pathways.

is the MFI, followed by LTA and a similar number of publications could be found about FAU and MOR. The heading “others” in the pie chart, which represents a 15%, corresponds to FER, BETA, MEL, ZSM-11, and related materials like ETS-10 or ETS-4. The different applications of these zeolites in pervaporation include alcohol dehydration, water removal in acid solutions, organic dehydration separations such as water/tetrahydrofuran, water/dioxane or water/dimethylformamide, removal of organics from water and organic/organic separations such as methanol/MTBE or *p*-xylene/*o*-xylene. In the following sections the mechanism of pervaporation in zeolite membranes are briefly described and the details about the different applications are provided.

### 10.5.1 PERVAPORATION MECHANISM IN ZEOLITES

The different mechanisms that operate in the separation of gases have been previously described in Section 10.4.1. In pervaporation, the transport mechanism can be described by an adsorption–diffusion mechanism [74,114] similar to one for polymeric membranes [115]. However, it is necessary to consider that the specific interactions between the permeating component and the zeolitic material are different in zeolites. Moreover, the diffusion through the ordered zeolite nanopores is different than in the dense organic matrix.

Two important considerations that appear in zeolite membranes should be taken into account for the transport of the molecules through the membrane [113]:

1. Zeolite membranes are formed by a polycrystalline layer, which means that the permeation is not only through the ordered nanopores of the zeolite crystal, intracrystalline pathways, but also through the spaces between the crystals, intercrystalline pathways (see Figure 10.20). Nomura et al. [116] proposed a model taking into account this consideration.
2. Surface of the zeolite crystal is full of siloxane groups, and hydrophilic molecules can take advantage of this and also adsorb into the intracrystalline spaces enhancing the permeance of the hydrophilic molecule. This special feature is an advantage for hydrophilic/hydrophobic separations, and makes the organic/water separations with hydrophobic zeolites more difficult.

These two special features make the modeling issue of pervaporation through zeolite membranes a very challenge topic. It is generally assumed that the diffusion of the species through the zeolite pores can be modeled using the dusty gas model and the M–S equation to correlate the chemical potential with the permeation flux. Considering this model and that there is no counterdiffusion, the adsorption of the species follows Langmuir isotherm, and there is single-file diffusion of molecules through the cages and presence of trace amount of solvent species inside the cages, the flux could be expressed as [114]

$$J_i = \frac{\rho_S \varepsilon D_{i,V}^S(0)}{\delta} (q_{i,f} - q_{i,p})$$

where

$J_i$  is the flux of the component  $i$

$\rho_S$  is the zeolite membrane density

$\varepsilon$  is the porosity of the membrane

$D_{i,V}^S(0)$  is the intracrystalline surface diffusivity

$\delta$  is the thickness of the membrane

$q_{i,f}$  and  $q_{i,p}$  are the adsorbed quantities of component  $i$  on the zeolite membrane at the feed and the permeate side, respectively

A simple model that relates the flux of the component with the driving force, which is the fugacity, has been proposed [74,113,114].

$$J_i = K_i(\hat{f}_i^f - \hat{f}_i^p)$$

In the liquid feed side, the fugacity,  $\hat{f}_i^f$ , could be obtained with the molar fraction,  $x_i$ , the activity coefficient  $\gamma_i$  and the saturated partial pressure of the component at the operating temperature  $P_i^s$ . In the permeate side where the component  $i$  is in the gas phase, fugacity is the result of multiplying  $y_i$  molar fraction of component  $i$  in the permeate by pressure in the permeate side. The following equation is obtained:

$$J_i = K_i(x_i\gamma_iP_i^s - y_iP_p)$$

The constant  $K_i$  is an overall mass transfer coefficient that includes diffusion and adsorption coefficients divided by the membrane thickness.

Finally, it is important to notice the effect of the support in the pervaporation flux, analyzed by Bruijn et al. [117] who proposed a model and evaluated the contribution of the support layer to the overall resistance for mass transfer in the selected literature data. They found that in many cases, the support is limiting the flux; the permeation mechanism through the support corresponds to a Knudsen diffusion mechanism, which makes improvements in the porosity, tortuosity, pore diameter, and thickness necessary for an increase in the pervaporation flux.

### 10.5.1.1 Adsorption: Hydrophobicity and Hydrophilicity

As we have seen previously, the separation mechanism in pervaporation is explained by an adsorption–diffusion process. In this way, the selective adsorption of the components in the zeolite will be responsible for the selectivity in the separation. Adsorption is an exothermic nonactivated process. In general, the isotherm of adsorption on zeolites follows a single site Langmuir-type isotherm [74].

$$q = \frac{q_{\text{sat},i}b_i\hat{f}_i}{1 + b_i\hat{f}_i}$$

where

$q$  is the quantity of gas adsorbed at a given fugacity,  $\hat{f}_i$

$q_{\text{sat},i}$  is the quantity of gas adsorbed when the entire surface is covered with a monomolecular layer

$b_i$  is the Langmuir equilibrium constant

The heat of adsorption is related to the affinity of the component to the surface; a high heat of adsorption means that the zeolite strongly adsorbs this component. The adsorption measurement implies many difficulties as was pointed out by Bowen et al. [113], and the different techniques employed—microcalorimetry, gravimetric, chromatography, and transient permeation—give rise to different values.

Generally speaking, two terms, hydrophobic and hydrophilic, are employed in pervaporation in zeolite membranes, to refer to the affinity of organophilic and water molecules, respectively, toward the zeolite. In this way, a hydrophilic zeolite adsorbs and preferentially permeates water. Gyaya et al. [118] defined a hydrophobicity index (HI), which is the ratio between the amount of organic and the amount of water that a solid adsorbs:

$$\text{HI} = \frac{q_{\text{organic}}}{q_{\text{water}}}$$

The adsorbed amount should be measured at the same conditions that actually are not specified in this definition. However, this hydrophobic index could be very useful for comparison purposes of different zeolites that are later discussed in this chapter.

The hydrophobicity and hydrophilicity character of a zeolite depends on many factors; one of the most important is the Si/Al ratio. The introduction of the trivalent Al in the structure needs to be compensated by adding a cation; the electrostatic forces between the negative charge framework and the cation also attract polar molecules [113]. Moreover, for a given zeolite structure, the Si/Al ratio could also be varied, as in the isomorphs of the MFI structure, ZSM-5, and silicalite-1 [119]. Silicalite-1 with a Si/Al ratio equal to infinity is the most hydrophobic zeolite, and this zeolite will separate organic compounds from water [116,120–126] or organic compounds with different polarity [119,127,128]. On the other hand, zeolite A possesses a ratio of Si/Al=1, which makes this zeolite the most hydrophilic, as a consequence it is employed in the separation of water/organic mixtures (see Section 10.5.2.4). It is important to note that as the Al content increases, the stability of the zeolite in acid medium decreases. This fact moved the researchers to study other zeolites with an intermediate Si/Al ratio that could resist acid medium. Zeolites like mordenite [129], zeolite T [130–132], and ZSM-5 [129] were synthesized and studied in acidic conditions.

### 10.5.1.2 Diffusion

Activated surface diffusion or configurational diffusion occurs in molecules with a diameter larger than 60% of the pore diameter, as is the case in pervaporation with zeolite membranes [113]. Diffusion is an activated process and the diffusivity follows an Arrhenius-type equation:

$$D = D_0 \exp\left(-\frac{E_d}{RT}\right)$$

The diffusivity of a molecule gives an idea about its mobility, how fast it is permeating through the membrane, and this value will be very useful for predictions of separations and fluxes. The calculations of diffusivities in pervaporation lead to several difficulties, and arising from those, there are different experimental techniques: pure vapor uptake measurements and liquid chromatography. In the first case, the coverage of the zeolite is smaller than in pervaporation where the liquid is in contact with the membrane, so the liquid chromatography method seems to be more realistic with respect to zeolite coverage. A new isotopic-transient pervaporation method has been employed to measure diffusivities in Ge-ZSM5 membranes [73]. This method also accounts for one of the problems in determining diffusivities which is the measurement in multicomponent mixtures. The results obtained for the MeOH/EtOH mixture are in accordance with the results obtained with the molecular dynamics simulations using the M-S model and the experimental observations. Table 10.2 shows the values of the calculated apparent diffusivities of the pure components and of the components in the mixture; in the pure component the large molecule of ethanol diffuses slower than the small molecule of methanol; however in the mixture, the ethanol speeds up and inhibits the diffusion of methanol (see Section 10.4.1.2).

The third problem associated with the measurement of diffusivities in zeolite membranes is related to the fact that the membrane is a polycrystalline layer that possesses intercrystalline defects and diffusion also takes place through these random defects.

## 10.5.2 APPLICATIONS

### 10.5.2.1 Alcohol Dehydration: Zeolite A

Alcohols and water form azeotropes at different compositions (see Table 10.3) [133] characterized by low-water content. In pervaporation it is important to remove the species present at low concentrations, because heat transfer and the amount of

energy required for this operation becomes substantial if large quantities are removed [113]. The zeolite most commonly employed for water removal from alcohols is zeolite A. It is a highly hydrophilic zeolite, due to its low Si/Al ratio, and it has a small pore opening of 0.41 nm, bigger than the kinetic diameter of water but smaller than many alcohols [74]; these features make zeolite A the best candidate for the dehydration of alcohols. Since the pioneering work of Kita [134] in 1995, patented by the Mitsui Shipbuilding & Co., Ltd. [135], many authors have attempted to synthesize and test zeolite A membranes for the dehydration of alcohols. Table 10.4 collects the results for the dehydration of ethanol, obtained by several authors. Kita et al. in 1995 patented zeolite A with a 30  $\mu\text{m}$  thickness that clearly outperforms the results obtained up to now, except for the case of Berg et al. [136] using a UV-exposed TiO<sub>2</sub>-coated metal support. They synthesized a well-intergrown thin zeolite layer, 3.5  $\mu\text{m}$ , over a flat support and their flux, obtained with a 5/95 wt% H<sub>2</sub>O/EtOH mixture at 45°C, which was 0.896 kg/m<sup>2</sup> h, was more than twice the flux obtained by Kondo et al. [137] using the same mixture at 50°C, which was 0.396 kg/m<sup>2</sup> h.

Santamaría and coworkers attempted to develop new methods for an easy scale-up of zeolite membranes. Tiscareño-Lechuga et al. [38] synthesized zeolite A membranes under a centrifugal force field. The zeolite layer was synthesized in the lumen of the tubular support, to protect the zeolite layer. A brushing method was employed to seed the support and after two syntheses, the pervaporation results showed a high water flux membrane. Pina et al. [35] used a semicontinuous method to decrease the number of synthesis necessary to achieve a defect-free layer. They obtained very good membranes with high selectivities; however, the fluxes were still lower than those obtained by Kondo [137]. Finally Pera-Titus et al [37], using the centrifugal force field and a controlled seeding method that consisted of a cross-flow filtration of a seed solution, found an optimum for the seeded weight gain of 0.4 mg/cm<sup>2</sup>. The results in pervaporation showed similar fluxes than those of Kondo et al. However, the calculated separation factor of 500 was smaller.

Huang et al. [140] also developed a vacuum seeding method that resulted in a 6  $\mu\text{m}$  zeolite layer that separates a mixture 5/95 = H<sub>2</sub>O/*i*-PrOH at 343 K with a separation factor >10000 and a water flux of 1.67 kg/m<sup>2</sup> h. The optimal conditions corresponded to a solution of a concentration of 7 g/L, with seeds of 3000 nm, and the vacuum applied for the seeding was 0.0150 kPa during 90 s.

Table 10.4 also shows the values obtained by Kondo et al. [137], with varying ethanol concentrations at different temperatures. As the concentration of water in the feed increases, the separation factor increases. The water adsorbs in the inter- and intracrystalline pores of the zeolite A, hindering the permeation of ethanol, which typically occurs up to a value around 10 wt% of H<sub>2</sub>O where there is no more increase, as it was observed by several authors [115,141]. The water flux increases as the water concentration increases, because the driving force for pervaporation increases. The temperature does not affect significantly the separation factor; however, the flux rises markedly since the mobility and diffusion of the molecules increases with temperature, due to surface diffusion is a temperature-activated process.

The separation of other alcohols different from ethanol has also been studied by Okamoto et al. [141] who found out that the separation factor increases in the order *i*-PrOH > *n*-PrOH > EtOH > MeOH as the kinetic diameter decreases. The methanol

molecule (0.38 nm) is smaller than the pores of the zeolite A and could enter the pores, decreasing the separation factor and the water flux.

### 10.5.2.2 Alcohol Dehydration: Other Zeolites

Zeolites different from zeolite A have also been employed in the dehydration of alcohols, such as FAU structure with zeolites X and Y [106], ZSM-5 [119,142], MOR [142–147], T [130,131] and also zeolite related materials, ETS-4 [24] and ETS-10 [27]. The published results are shown in Table 10.5. Separation factors and water fluxes are smaller than those in zeolite A. This behavior was expected since zeolite A is the most hydrophilic, which results in higher water fluxes; also, the pore opening in zeolite A is smaller than the alcohol kinetic diameter, which makes it shape selective, and this does not occur in the other zeolites. The Si/Al ratio is higher and makes them more stable under acidic conditions. The highest separation factor could be observed for the zeolite T and the mordenite prepared by Zhang et al. [144]. This result could be explained based on the different structures [113]; FAU structure possesses only 12-membered ring (MR) pores whereas zeolite T (OFF structure) and MOR possesses, in addition, 8-membered ring pores which lay perpendicular to the 12-MR pores. As the zeolite layer is randomly oriented these 8-MR provide an alternative pathway to water, hindering ethanol diffusion and giving rise to higher selectivities for MOR and T.

### 10.5.2.3 Water Removal in Acid Solutions

Although the performance of zeolites different than zeolite A is lower, the acid stability of these zeolites is higher than that of zeolite A and makes them good candidates for the separation of acid mixtures. Both, the separation of water in the esterification reaction for equilibrium displacement in a membrane reactor, and the separation of the water/acetic mixture, required a water permeable acid-resistant membrane. The most promising results concerning separations in acid medium have been obtained with zeolite T [130–132] and MOR [147]. Li et al. [147] synthesized MOR in the outer part of an  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> support, and studied the effect of crystallization time on the separation of water/*i*-propanol mixtures (10/90 wt%). All the membranes showed a high-separation factor around 4000, and as the synthesis time increased the water flux decreased, due to the increase in the membrane thickness. The membrane obtained after 2 h synthesis time was tested in a water/acetic acid mixture (50/50 wt%) at 80°C. A separation factor of 900 and a water flux of 0.67 kg/m<sup>2</sup> h were obtained. The effect of temperature, from 40°C to 90°C, and that of concentration from 50 to 90 wt% of acetic acid in the feed were also studied. The flux of water and acetic acid increased with temperature, due to an increase in the partial vapor pressure, which is the driving force for pervaporation. A linear dependence between the partial vapor pressure and the water and acetic acid fluxes was obtained. At high acetic acid concentration, 90 wt%, the separation factor decreases to almost 50. After the exposure to this mixture, the membrane was cleaned with pure water and tested again in a 50/50 wt% water/acetic acid mixture at 80°C showing a water flux of 0.614 kg/m<sup>2</sup> h, similar to the one obtained previously, and a slight decrease in the separation factor, resulting in a final value of 299. The authors concluded that this decrease was not related to a deterioration of the membrane. The decrease in separation

factor with the acetic acid concentration could be explained by an association of water and acetic acid molecules that lowers the amount of water adsorbed in the zeolite.

For a zeolite T (OFF structure, 0.68 nm XRD pore diameter), Tanaka et al. [131], observed that the separation factor of a water/acetic acid (50/50 wt%) measured at 75°C decreased monotonically after the immersion of the membrane into the acetic acid mixture. Initially, the separation factor and water flux were 182 and 1.46 kg/m<sup>2</sup> h, respectively, and after 32 h these values changed to 86 and 1.77 kg/m<sup>2</sup> h, showing a deterioration of the membrane. Cui et al. [130] also studied the stability of crystals and membranes of zeolite T in acid medium. The powders were immersed in a 50/50 wt% water/acetic acid mixture for 7 days at 75°C and also in HCl solutions 0.5 and 1 M for 1 h at 50°C. The analysis of the samples after the treatment by ICP and XRD indicated that the sample treated in the acetic acid solution maintained its original Si/Al ratio equal to 4; however, the hydrochloridric acid treatment with the 1 M solution destroyed the zeolite structure and the 0.5 M solution dealuminated the zeolite to a Si/Al equal to 8.9 and the XRD analysis corresponded to zeolite T. The membrane performance, after being used for 1 week at different water/acetic acid concentrations, remains almost unchanged and the separation factor of the membrane treated in HCl dramatically decreased as was expected.

The pervaporation of water/acetic acid mixtures was also evaluated with ZSM-5 membranes by the Matsukata group [129]; the initial values of the separation factors in a 50 wt% acetic acid aqueous solution were around 10 to 20 due to the preferential adsorption of acetic acid which decreased the amount of water adsorbed. To increase the amount of water adsorbed, a surface modification that consisted of an alkali treatment with NaOH was carried out. After the treatment, the water flux and separation factor increased markedly, reaching values up to 381 and 0.783 kg/m<sup>2</sup> h, respectively.

Masuda et al. [149] also prepared a hydrophilic acid-proof silicalite-1 membrane by removing the template using a liquid-phase oxidation method with hydrogen peroxide. The selective permeation of water molecules occurred through the silanol groups formed in the micropores of the silicalite and in the intercrystalline defects of the membrane, obtaining very low fluxes of water ( $2 \times 10^{-4}$  kg/m<sup>2</sup> h). Kalipcilar et al. [150] prepared a SSZ-13 membrane able to break the azeotrope of H<sub>2</sub>O/HNO<sub>3</sub>, the permeate concentration was 38.3 wt% HNO<sub>3</sub>, and the total flux was 0.12 kg/m<sup>2</sup> h at 25°C.

#### 10.5.2.4 Organic Dehydration

General-purpose organic solvents used in the chemical industry that are difficult to separate with conventional methods represent a potential area where pervaporation finds applications. The use of polymeric membranes in this case was not very successful due to the low chemical stability of the polymers in the organic solvent. The separations that have been accomplished up-to-date with zeolite membranes include tetrahydrofuran, dimethylformamide, and dioxane.

Tetrahydrofuran, THF, is an important industrial solvent and forms an azeotropic mixture at 5.3 wt% with water (see Table 10.3). To separate water/THF, Li et al. [148] tested the pervaporation performance of different hydrophilic zeolite membranes, zeolite A, zeolite Y, MOR, and ZSM-5. The preliminary test showed that the separation factor increased as the Si/Al ratio of the zeolite decreased, except for the case of zeolite A. This fact is probably due to the lower quality of this membrane with respect to the others; since in the permeation of triisopropylbenzene (TIPB), showed the highest flux, 3.1 g/m<sup>2</sup> h, indicating the presence of nonselective defects. Therefore, the best results were obtained with zeolite Y, rendering a separation factor of 300 with a water flux of 2.24 kg/m<sup>2</sup> h at 60°C. The water flux increased with water concentration in the feed, up to a value of 15 wt%, indicating that the zeolite was saturated, as was the same for the case of water/ethanol mixtures in zeolite A, previously described. At the same time, the separation factor decreases as water concentration decreased. The stability of the membrane was also studied, showing a stable performance after 35 h of operation.

Urtiaga et al. [151] studied the dehydration of industrial solvents, THF and acetone, using a commercial zeolite A membrane (SMART Chemical Company Ltd., United Kingdom). As it was previously pointed out, the separation factor strongly depends on the water concentration in the mixture, achieving a maximum separation factor of 20,000 at 0.8 wt% of water in the feed. In general, separation factors are higher than those obtained by Li et al. [148]. However, water fluxes are smaller despite the water flux increases 2.4 times when the temperature increases from 45°C to 55°C (see Table 10.6). Better results were also attained for a water/THF (10/90) wt% mixture with an inorganic silica–zirconia membrane [152], a separation factor of 2200 and a water flux of 7.2 kg/m<sup>2</sup> h was achieved.

Okamoto et al. [141] studied several water/organic systems that are listed in Table 10.6, and the performance of the zeolite A membrane was excellent for all the separations. These results could be also compared with the ones obtained using microporous silica membranes [153]. Silica membranes, for a water/dioxane (10/90 wt%) mixture at 60°C, showed a separation factor of 125 and a water flux of 2.2 kg/m<sup>2</sup> h. For dimethylformamide, (DMF), the results obtained for a mixture of water/DMF (13.2/86.8 wt%) were 30 and 0.225 kg/m<sup>2</sup> h for the separation factor and water flux, respectively. In both separations, zeolite A outperforms the microporous silica membrane.

#### 10.5.2.5 Removal of Organics from Water

Unlike the others this application demands a hydrophobic membrane; therefore, silicalite-1 with a Si/Al ratio equal to infinity is the most studied for the separation of ethanol from water, although the hydrophobic Ge-ZSM5 [154] and  $\beta$ -type membranes

**TABLE 10.6**  
**Pervaporation Performance in Organic Dehydration of Solvents with Zeolite Membranes**

Zeolite	Solvent (H <sub>2</sub> O wt%)	Temperature (°C)	Flux H <sub>2</sub> O (kg/m <sup>2</sup> h)	$\alpha_{A/B}$	Ref.
A	Dioxane (10)	60	1.87	>9000	[141]
A	DMF (10)	60	0.95	>9000	[141]
A	Acetone (10)	50	0.91	5600	[141]
A	Acetone (5)	50	0.83	6800	[141]
A	THF (6.7)	60	0.49	50	[148]
Y	THF (5)	60	2.1	360	[148]
Y	THF (6.7)	60	2.4	200	[148]
MOR	THF (6.7)	60	0.42	15	[148]
A	Acetone (10)	48	0.314	50	[151]
A	THF (7)	55	0.98	1240	[151]

have been also studied. The separation factors for the ethanol/water mixtures, with values from 10 to 125, and ethanol fluxes, with values from 0.1 to 0.3 kg/m<sup>2</sup> h, obtained with these membranes are far from the values obtained with the hydrophilic membranes for organic dehydration. The presence of silanol groups on the surface of the crystals and in between them (i.e., in the intercrystalline defects) contributes to the permeation of water, decreasing the organic/water selectivity and permeation flux of the organic component [113].

Bowen et al. [74] studied the separation of a wide variety of organic compounds in organic/water mixtures (5 wt %) using a Ge-ZSM-5 membrane. Different organic functional groups were studied: alcohols, aldehydes, carboxylic acids, esters, ethers, and ketones. The separation factor and flux linearly correlated with the fugacity of the organic component in the mixture, which is the driving force for pervaporation.

#### 10.5.2.6 Organic Separations

The synthesis of methyl-*tert*-butyl ether, MTBE, attracted much interest in the past years due to its use as an additive in gasoline; however, after the presence of MTBE in groundwater was observed, as the result of leaks in storage tanks, the Environmental Protection Agency [155] investigated and labeled MTBE as a “potential human carcinogen.” Since January 2004 some states in the United States, including New York and California, banned its use; although this is still a controversial issue since no carcinogenic effects have been demonstrated yet. The separation of MeOH from MTBE was first accomplished by Sano et al. [127] using a silicalite-1 membrane. Their results in pervaporation were above the vapor–liquid equilibrium curve, but the separation factors (4–10) and methanol flux (0.08–0.12 kg/m<sup>2</sup> h) were very low. The results obtained by Kita et al. [112] with zeolites Y and X improved markedly, showing methanol fluxes of 1.70 and 0.46 kg/m<sup>2</sup> h, respectively, and separation factors higher than 5300.

The separation of *n*-hexane/2,2-dimethylbutane, (DMB), another separation where size exclusion takes place, has been accomplished by Flanders et al. [156], using pervaporation and vapor permeation. Both, the *n*-C<sub>6</sub> and DMB fluxes are higher in the former case due to the higher driving force in pervaporation, leading to a lower selectivity compared to vapor permeation. The separation of xylene isomers on MFI membranes has been described in Section 10.4.2.1 as a separation where size exclusion takes place. The results of the separation of these isomers using pervaporation with FER membranes [20] and MFI [21] were not successful, and very low fluxes of 10<sup>-9</sup> and 10<sup>-7</sup> mol/m<sup>2</sup> s, accompanied by separation factors not greater than 16, respectively, were obtained. The best results for the pervaporation of xylenes were obtained by Yuan et al. [129] who prepared a template free silicalite-1 membrane, the separation factor for a 50/50 wt% mixture of *p*-xylene/*o*-xylene at 50°C was 60, and the flux of *p*-xylene was 13.7 × 10<sup>-2</sup> kg/m<sup>2</sup> h.

## 10.6 ZEOLITE-MEMBRANE REACTORS

Zeolite-membrane reactors belong to the area of inorganic membrane reactors, a field that started in the 1980s and has witnessed intense research activity during the last decade as is evident in several reviews [157–164]. Many catalytic processes of industrial importance involve the combination of high temperature and chemically harsh conditions, two factors that strongly favor inorganic membranes over their polymeric counterparts even though there is a large cost differential (ceramic membranes, which are generally used as supports for zeolite layers, are 10–100 times more expensive than polymeric ones [78]).

More specifically in the area of this overview, zeolite materials constitute the main group of microporous membranes with regard to their potential membrane-reactor applications. The wide variety of existing zeolite structures, together with the possibility of modifying their adsorption and catalytic properties, provides us with a working material of high flexibility. As a

**TABLE 10.7**  
**Classification of Inorganic Membrane Reactors**

Inert membrane reactors (IMRs)	The catalyst is located apart from the membrane structure
Catalytic membrane reactors (CMRs)	The membrane material itself is catalytic or becomes catalytically active during preparation by the addition of active precursors
Combined	There is a catalytic material both inside and outside the membrane

matter of fact, zeolite-membrane reactors have undergone an impressive expansion, thanks to the availability of procedures to prepare zeolite membranes and layers with sufficient quality and reliability.

Nevertheless, the development of zeolite-membrane reactors still requires improvements in the fluxes and separation factors attained to date, an objective to which many efforts have been devoted in recent years with the aim of materializing an industrial application of zeolite-membrane reactors. Several reviews have been published in the last 5 years dealing completely or partially with zeolite membranes [2,3,5,161,162,165–167]. Particularly, noteworthy have been the advances regarding the use of supports of different natures and characteristics (see Section 10.6.4), the control of the orientation and thickness of zeolite layers (see Section 10.2.1.2), and the preparation of new zeolite materials such as membranes (see Section 10.3). In spite of these advances, before zeolite-membrane reactors are used in industry (see Section 10.6.5), significant progress must be achieved in more prosaic issues such as scale-up and control of the synthesis process to increase membrane reproducibility.

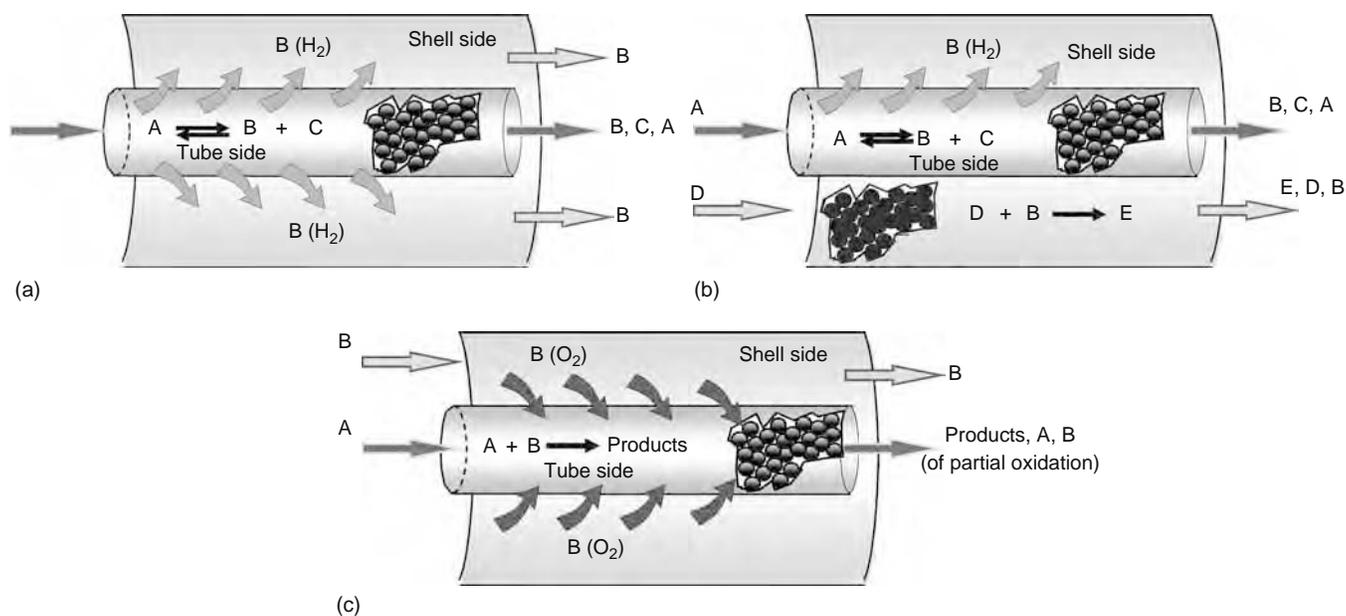

After a rapid revision of the general working principles of inorganic membrane reactors, comprehensively discussed in the previously quoted reviews; the present overview is focused on applications for already proposed inorganic membrane-reactor types as well as new reactor concepts involving zeolite membranes and coatings [5,6]. Starting from the general basis, we have selected recent developments (mainly over the last 5 years), from authors' point of view, to represent suitable illustrations of reactor concepts, interesting applications, or emerging ideas.

### 10.6.1 GENERAL CONSIDERATIONS ON INORGANIC MEMBRANE REACTORS

The concept of combining membranes and reactors is being explored in various configurations, which can be classified according to the role played by the membrane (see Table 10.7). Different membrane shapes can be used: flat discs, tubes (dead end or not), hollow fibers, metal gauze, foils, or monolith multichannel elements; but for simplification purposes all the reactor schemes shown here are for a tubular geometry. When an inert membrane reactor (IMR) is used, the catalytic material does not form part of the membrane. A typical configuration is a tubular membrane enclosing a fixed bed of catalyst. In this case, the membrane does not participate in the reaction directly, but it is used to add (reactant distribution) or remove (product removal) certain species from the reactor. The most widely used application involves equilibrium displacement by the removal of at least one reaction product, which preferentially (mesoporous membranes) or selectively (dense membranes) permeates through the membrane (see Figure 10.21a). The equilibrium constant does not change, but the product is removed from further contact with the catalyst so that a reverse reaction cannot occur. Most often, the removal of  $H_2$  in dehydrogenation reactions has been the process of choice, although other processes such as decomposition or syngas production have also been studied. Equilibrium displacement can be enhanced through reaction coupling (see Figure 10.21b) on both sides of the membrane where complementary processes are carried out. The reactions often use different catalysts, which are packed on opposite sides of the membrane.

A second application of IMRs consists of using the membrane to distribute a reactant to a fixed bed of catalyst packed on the opposite side (see Figure 10.21c). The most frequent case corresponds to a series-parallel reaction network where there is a favorable kinetic effect regarding the partial pressure of the distributed reactant. Thus, IMRs have been used successfully as oxygen distributors in many oxidations; where not only greater selectivity with respect to conventional arrangements is obtained but also a safer operation where a reduced formation of hot spots, lower probability of runaway, and catalyst life enhancement are achieved.

For catalytic membrane reactors (CMRs), the catalytically active membrane often acts as a contactor in which the diffusion of reactants through a finite catalytic layer inside the porous structure takes place. The concept can be used with an opposing reactant mode or with a forced flow mode. In the former case (see Figure 10.22a), the catalytic membrane is used to keep reactants segregated on its either side providing a safer operation which is really important for oxidation processes. Suitable operation conditions provide us with a catalytic-engineered reaction zone where reactants are in a stoichiometric ratio preventing their slip to the opposite side and minimizing further reaction to undesired by-products by controlling the residence time of the products. This configuration has been applied to both equilibrium (alkenes hydrogenation) and irreversible reactions (partial oxidations, wet air oxidation of organic contaminants). In particular, triphasic (gas/solid/liquid) reactions (see Figure 10.22b), which are limited by the diffusion of the gaseous reactant into the liquid phase up to the catalytic surface, are significantly improved by using this concept [168–173].

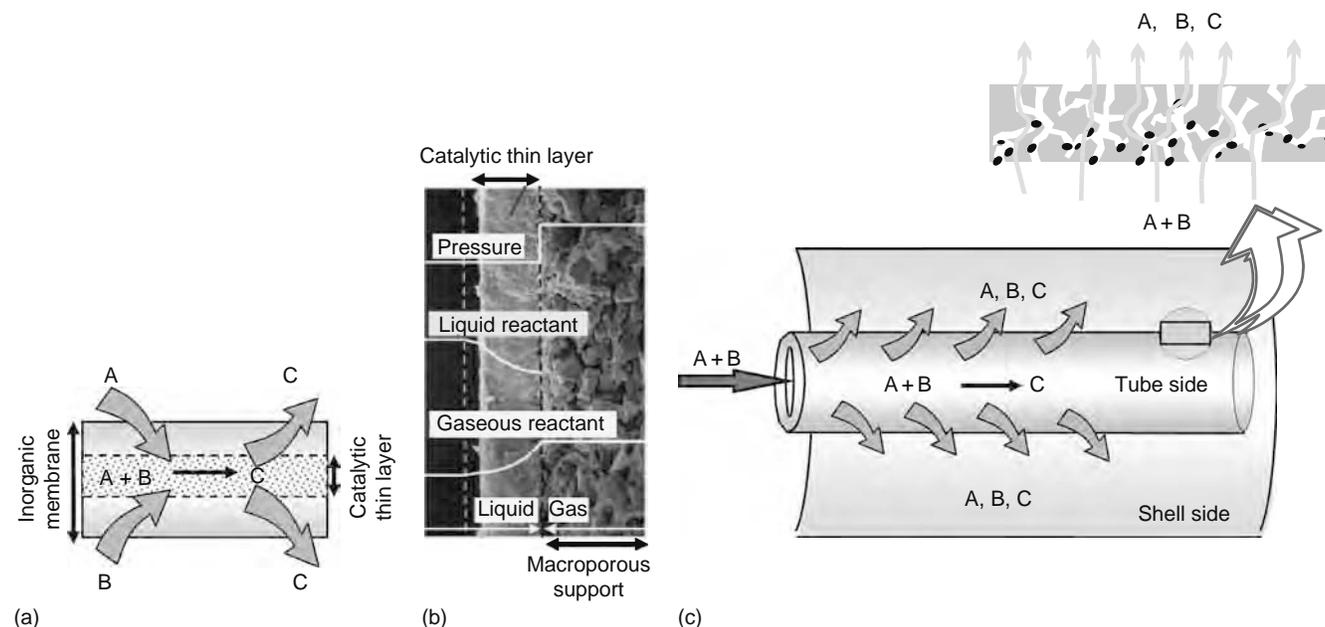

**FIGURE 10.21** (See color insert following page 588.) Traditional applications of inorganic membrane reactors for (a) conversion enhancement by product removal, (b) permeation of products and reaction coupling, and (c) selectivity enhancement by reactant distribution.

Finally, in catalytic membrane reactors operating in flow-through configuration (see Figure 10.22c), largely investigated for enzyme-catalyzed reactions, a premixed feedstream is forced to permeate through the catalytic membrane with the objective of attaining higher conversions by decreasing mass transfer resistances at the expense of a significant pressure drop.

### 10.6.2 TRADITIONAL APPLICATIONS OF ZEOLITE-MEMBRANE REACTORS

It has been considered traditional applications of zeolite-membrane reactors those based on reactor concepts already demonstrated using mesoporous or dense membranes. These include conversion enhancement by equilibrium displacement or by the removal of inhibitors, and selectivity enhancement by reactant distribution. For such cases, the zeolite membrane is usually catalytically inert and is coupled with a conventional fixed bed of catalyst placed on one of the membrane sides.

**FIGURE 10.22** (See color insert following page 588.) Applications of catalytic membrane reactors as (a) contactors using opposing reactant mode, (b) interfacial contactors for triphasic reactions, and (c) efficient gas–solid contactor using forced flow mode.

### 10.6.2.1 Zeolite-Membrane Reactors for Conversion Enhancement by Product Removal

The removal of products to increase conversion in equilibrium-limited reactions is indeed one of the first applications that comes to mind when considering membranes in a reaction environment. To make beneficial the use of the membrane reactor, the membrane employed must be able to separate preferentially at least one of the products from the reaction mixture, at a reasonable rate and selectivity. If the selectivity of the membrane is insufficient, reactant loss will become significant and the overall conversion in the membrane reactor will be lower than in a conventional packed bed reactor. If the permeation rate is insufficient, the ratio between the membrane surface area required and the volume of the catalyst bed will become unrealistic.

With the development of zeolite membranes, the field of possible applications has become much broader. Successful reaction-product separation by zeolite membranes is governed by differences in the affinity of the components with the zeolite framework or by differences in the mobility of the components in the zeolite framework; i.e., besides molecular sieving and differences in diffusivities, differences in adsorption appear to be a key factor in separation selectivity [61,174].

The membrane group at IRC (Institute on Research of Catalysis, Lyon, France) has studied intensively isobutane dehydrogenation in a fixed catalytic bed using MFI membranes to permeate hydrogen [175–177]. Silicalite-1 membranes were synthesized hydrothermally [178,179] in the macroporosity of  $\alpha$ -alumina tubular supports to minimize long-range stresses during thermal cycling and to limit the maximum size of defects to the pore of the host. One of the interesting results of these studies was the realization of the need to develop specifically very active catalysts able to keep up with the high extraction ability of the membrane. Thus, catalysts designed for fixed bed operation may not be suitable for use in membrane reactors, where the reactive environment is different (deactivation phenomena may arise) and where there is a clear need to tailor the catalytic activity to match the permeation capabilities of the membrane. The need of an adapted catalyst for use in membrane reactors may be a general requirement of membrane reactors, which perhaps has received less attention than that dedicated to membranes. These authors also stressed the negative effect of reactant (isobutane) loss when the membrane is not selective enough to avoid it.

The catalytic dehydrogenation of cyclohexane in an FAU-type zeolite-membrane reactor packed with a 1 wt% Pt/ $\text{Al}_2\text{O}_3$  catalyst has been studied by Jeong et al. [180,181]. The conversion of cyclohexane in the membrane reactor is increased beyond the equilibrium value (32.2% vs. 72.1% at 473 K) due to the simultaneous and rapid removal of benzene and hydrogen from the reaction-site side by a sweep flow rate, although the separation factors for benzene over cyclohexane were not high enough at reaction temperatures (around 10). Furthermore, the results of the simulation for the membrane reactor in which  $\text{H}_2$  is co feed with cyclohexane demonstrate the coke inhibition by its relatively high-partial pressures in the reaction side. This is probably the most useful feature of zeolite-membrane reactors in comparison with their counterparts based on Pd dense membranes.

Zeolite membranes have also been used for hydrogen separation in syngas production. The study of  $\text{CO}_2$  reforming of methane over a catalytic membrane reactor at 700°C–750°C has been reported by Liu et al. [182,183] who used composite  $\text{La}_2\text{NiO}_4$ -NaY and  $\text{La}_2\text{NiO}_4$ -NaA catalytic membranes, respectively, with an enclosed packed bed of catalyst in the tube side. The randomly oriented zeolite membranes were prepared by in situ crystallization procedures over the internal asymmetric  $\alpha$ -alumina tubular supports, and subsequently were catalytically activated by impregnation of a La-Ni gel. For the as prepared NaY and NaA zeolite membranes, ideal  $\text{H}_2/\text{CH}_4$  separation factors at room temperature were 9.8 and 4.2, respectively; i.e., higher than the value 2.8 governed by Knudsen diffusion. However, separation factors for binary mixtures were not significantly high, not only CO and  $\text{H}_2$  but also  $\text{CH}_4$  and  $\text{CO}_2$ , diffused toward the outer tube of the zeolite membrane. To overcome this problem, the authors adopted a  $\text{La}_2\text{NiO}_4$ -composite zeolite membrane, so that there was methane conversion to syngas before permeation which led to conversion values higher (up to 21.4 mol%) than that of conventional fixed bed reactors. Moreover, the problem of catalyst deactivation due to whisker carbon formation (hard to avoid in a  $\text{CO}_2$  atmosphere) is partly resolved by adopting a membrane reactor in which the surface coking comes to an equilibrium and the performance of the catalytic membrane remains at a high level.

Ostrowski et al. [184] analyze the catalytic partial oxidation of methane at 700°C–750°C in a Ni/ $\alpha$ - $\text{Al}_2\text{O}_3$  catalyst enclosed as fixed bed or fluidized bed in a membrane reactor. The silicalite-1 membranes employed exhibited over more than 100 h of operation high thermal and mechanical stability. In both cases, the separation selectivity was low, mainly controlled by Knudsen diffusion, i.e., large amounts of methane were removed from the catalytic bed through the membrane and therefore, could not be consumed in the reforming steps. However, the stainless steel silicalite-1 immersed in a fluidized bed reactor rendered better separation selectivities to  $\text{H}_2$  but the permeation flux was not sufficient to shift significantly the equilibrium toward syngas. To estimate the permeation rates that are necessary for achieving a marked improvement of the syngas yield, these authors have developed a mathematical model [184] to simulate the membrane reactor performance under conditions relevant for industrial applications (5–30 bar and 750°C–800°C). The Peclet number, which is given by the ratio of the molar flow rates at the reactor inlet and the permeation side, necessary for  $\text{CH}_4$  conversion enhancement is also calculated.

The previous discussion illustrates the difficulties in attaining high gas-phase separation factors with zeolite membranes, even when good quality membranes are employed. In spite of these difficulties, van de Graaf et al. [185,186] managed to obtain a considerable increase in conversion (13% higher than the thermodynamic value under optimal operation conditions) and a very significant shift in product selectivity (a 34% increase in the ratio *trans*-2-butene/*cis*-2-butene) in the metathesis of

propene by using a silicalite-1 membrane supported on a flat stainless steel sheet and 16.4 wt%  $\text{Re}_2\text{O}_7/\gamma\text{-Al}_2\text{O}_3$  as a catalyst. This can be attributed to adsorption selectivity for *trans*-2-butene which is the strongest adsorbing component in the mixture able to block the pores of the zeolite for the permeation of propene (with selectivity in binary mixtures close to 5). These authors also compare the conversion in the membrane reactor with and without the presence of a pre-reactor to equilibrate the feed, making it clear that reactant loss is significantly suppressed by feeding the reactor with an equilibrated mixture.

In general, most of the high-separation factors reported for zeolite membranes are associated with pervaporation processes (see Section 10.5) or with vapor-separation applications where the permeated component is preferentially adsorbed. This has given rise to a variety of works in which the membranes have been used for equilibrium displacement by selective product permeation. The largest group probably corresponds to esterification processes, where hydrophilic zeolite membranes are employed to remove the product, water, replacing the extensively studied polymer membranes [187–192].

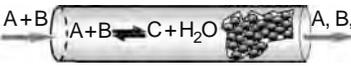

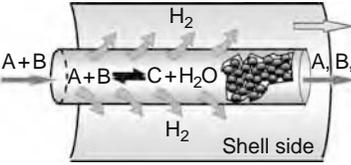

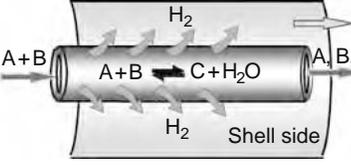

Among the publications related to this subject, Jafar et al. [139] used a tubular NaA zeolite membrane prepared on a carbon–zirconia support in the vapor space of an esterification reactor to remove the product, water, formed in the reaction of lactic acid with ethanol catalyzed by *p*-toluenesulfonic acid. This protected the sensitive zeolite A membrane from acid attack, and still allowed high-permeation fluxes responsible for the enhanced yields of ethyl lactate. Recently, Budd et al. [193] have applied a NaA/polyelectrolyte multilayer-pervaporation membrane showing a greater stability under acidic conditions in comparison with a pure zeolite A membrane and maintaining a high selectivity for water over alcohols. For the same purpose, Tanaka et al. [131,132] proposed a zeolite T membrane, prepared by *ex situ* crystallization [130], for the pervaporation-aided or vapor permeation-aided esterification of acetic acid with ethanol. This membrane has a higher acid resistance and can be directly immersed in the liquid-phase reaction mixture. The conversions achieved exceed the equilibrium limit and reached to almost 100% after a stabilization period of 8 h. Another acid-resistant zeolite with a high-potential applicability in acid–environment reactions is mordenite, which has recently been prepared as a membrane on tubular supports [142–147].

The use of zeolite membranes in esterification reactions was taken a step further by Bernal et al. [194], who used a catalytically active H-ZSM-5 zeolite membrane to carry out the esterification of acetic acid with ethanol. In this work, a closer integration of reaction and separation was sought to minimize the transport resistances present in fixed bed reactors enclosed in inert membranes. In this more traditional type of membrane reactor the products formed on the catalyst must desorb, diffuse to the membrane surface, and transport to the permeate side. Conversely, when a catalytic membrane is used, the products can be removed as soon as they are formed, displacing the local equilibrium and achieving a higher turnover rate. As an example, Figure 10.23 summarizes the results of the study. It can be seen that the conversion obtained at the same feed rate and catalyst loading was greater in noncatalytic membrane reactors (H-ZSM-5 powder catalyst + Na-ZSM-5 membrane) compared to conventional fixed bed reactors (H-ZSM-5 powder catalyst). However, the conversion was further increased with the catalytic zeolite membrane (H-ZSM-5 membrane), which clearly outperformed the catalyst + inert membrane configuration.

Water was also the targeted species in two other reacting systems that will be discussed next. Both correspond to the synthesis of tertiary ethers, i.e., typical examples of equilibrium-limited reactions where the conversion is generally low due to the limits imposed by thermodynamic equilibrium and where the presence of water has a strong inhibiting effect on the catalytic activity [194,195]. Therefore, these examples could be also included in the next section of conversion enhancement by inhibitors removal [196].

Aiouache and Goto [197] coupled a zeolite NaA membrane and a reactive distillation column during *tert*-amyl alcohol etherification with ethanol. The reacting system is complex with several azeotropes and two important side reactions. The study of residue curve maps showed that the azeotropes, where water as a component could be broken by pervaporation, while at the same time displacing the reaction equilibrium. As expected, the experimental study demonstrated significant gains in *tert*-amyl ethyl ether (TAEE) yield when the zeolite membrane tube was placed inside the distillation column. Salomón et al. [198] used Amberlyst enclosed in the annular space of hydrophilic zeolite membranes (mordenite and zeolite NaA) for the gas-phase production of methyl-*tert*-butyl ether (MTBE) from *tert*-butyl alcohol and methanol. In experiments where mixtures of the main components were present in the reactor, it was shown that water, being the most polar component, was adsorbed preferentially, and the separation selectivity obtained with respect to the other components depended inversely on the polarity of the permeating species. The selective permeation of water increased conversion beyond that attainable in a fixed bed reactor. At the same time, in the experiments with mordenite membranes, the permeance of MTBE was between 30% and 50% higher than that of isobutene (an undesired product in this system), leading to a significant enhancement in MTBE selectivity. The increase in conversion and selectivity gave rise to MTBE yields which were 6.7% points above the equilibrium predictions.

$\text{CO}_2$  hydrogenation into methanol is considered today as one of the promising methods to mitigate the greenhouse effect [199]. Barbieri [200] and Galluci [201] have studied theoretically and experimentally  $\text{CO}_2$  conversion into methanol under industrial conditions (200°C–263°C, 20–24 bar) using a fixed bed of  $\text{CuO-ZnO/Al}_2\text{O}_3$  catalyst enclosed in a zeolite-membrane reactor. The use of A-type zeolite-membrane reactors as substitution for traditional reactors is aimed at increasing  $\text{CO}_2$  conversion since, in principle, in a gas–vapor mixture ( $\text{CO}_2$ ,  $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CH}_3\text{OH}$ ,  $\text{H}_2\text{O}$ ) vapors can preferentially permeate through zeolite membranes. They concluded that the selective removal of methanol was effective in reducing the rate of the reverse reaction and also in increasing the turnover rate, via accelerated desorption of methanol and water. An increase of selectivity was also expected by reducing the incidence of the competing reaction producing carbon monoxide. Particularly,

Reactor Type	Reactor Configuration	Reactant Conversion <sup>a</sup> (%)	Equilibrium Displacement <sup>b</sup> (%)
Fixed bed reactor		49.4	—
Inert zeolite membrane reactor		56.9	2.4
Catalytic zeolite membrane reactor		63.1	5.6

<sup>a</sup> Equimolar feed (ethanol/acetic acid) at 359 K

<sup>b</sup> Quaternary feed in equilibrium at 338 K

with regard to the methanol yield, the experimental results showed that the zeolite-membrane reactor gives the highest value, 8.7%, compared to a corresponding value of 2.4% for traditional reactor and 2.5% of the lithiated Nafion membrane reactor studied by Struis [202,203].

### 10.6.2.2 Zeolite-Membrane Reactors for Conversion Enhancement by Removal of Catalyst Poisons/Inhibitors

Applications in this field are, as could be expected, system-specific and take advantage of the particular features and operating conditions of the reaction environment. Espinoza et al. [204] used different zeolite membranes for in situ water removal under typical conditions of Fischer–Tropsch synthesis. In this system, water, a reaction product, is able to oxidize cobalt and iron-based catalysts, causing deactivation. In addition, water has an inhibiting effect on the rate of reaction over iron-based catalysts. Selective water removal with hydrophilic zeolite membranes in this system presented significant challenges due to the high temperatures involved (200°C–350°C), as the interaction between the zeolite and the adsorbed water weakens as temperature increases. However, high-partial pressures of water are also present, which help to compensate for the effect of temperature. As a result, satisfactory water/H<sub>2</sub> and water/hydrocarbon separation factors could be obtained, even at temperatures of 250°C and above.

Xiongfufu et al. [205] used Fe-MFI and MFI membranes supported on alumina tubes to carry out the dehydrogenation of ethylbenzene to styrene. The Fe-MFI membranes were prepared by in situ insertion of ferrum species during the hydrothermal treatment to combine catalysis with separation. The H<sub>2</sub>/propane separation factor quoted for the as prepared substrates at 25°C was moderately high (25.8), showing a good molecular sieving effect improved by the incorporation of ferrum species into the zeolite framework. When the Fe-MFI zeolite membrane was applied to ethylbenzene dehydrogenation at 600°C, a 15% and 5% increase in conversion and selectivity, compared with the fixed bed reactor, was observed, respectively, under certain experimental conditions. As such, this work would belong to the previous section on equilibrium enhancement. The reason discussed here is that, according to the findings of this work, the amount of styrene adsorbed on the Fe-MFI membrane was much lower than on its MFI counterpart, leading to a faster removal of the product. The authors concluded that this helped to achieve a higher conversion by preventing carbon deposition on the Fe-MFI membrane. XRD analysis of the used and fresh

membranes showed no change in the overall structure of the membrane, although minor changes have been observed for H<sub>2</sub>/N<sub>2</sub> separation factors, probably due to the pore growth in the presence of water steam at the reaction temperature.

Finally, Nomura et al. [120] used an organophilic silicalite-1 membrane supported on a porous stainless steel disk for the selective pervaporation of ethanol from a fermentation reactor at 303 K. Glucose medium with dry baker's yeast was used for the fermentation broth. In this case, the advantage of using the zeolite membrane was twofold: on the one hand, continuous removal of ethanol enabled the system to operate continuously, avoiding ethanol inhibition by keeping it at a low concentration. On the other, it produced a highly concentrated outlet stream (81%–98%, depending on the ethanol concentration of the broth), which cannot be obtained in conventional fermentation reactors as a result of the relatively high ethanol–water separation factors achieved (from 85.9 to 218).

### 10.6.2.3 Zeolite-Membrane Reactors as Reactant Distributors for Selectivity Enhancement

The concept of reactant distribution was intensely investigated with mesoporous membranes (see Refs. [162,163]), mainly for applications in selective oxidations in instances where low-partial pressures of oxygen would favor the selective oxidation vs. total oxidation. Under these conditions, distributing oxygen was beneficial and the possibility of increasing selectivity by oxygen distribution has been demonstrated for many reactions and for both inert and catalytically active membranes.

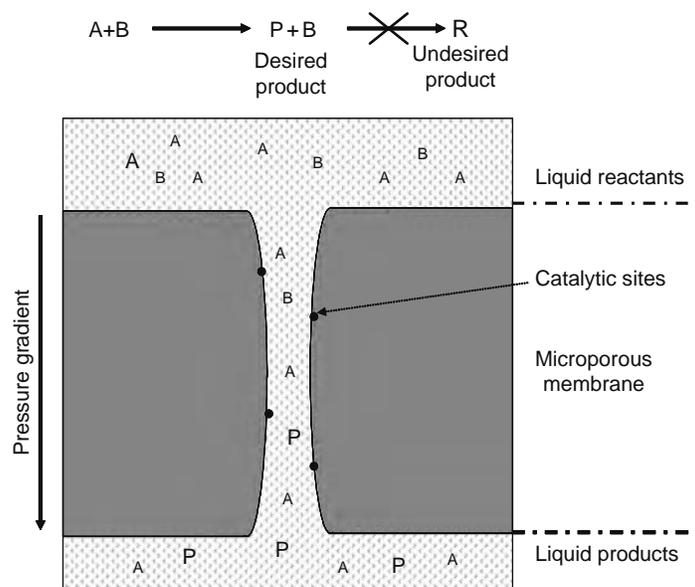

There have been a few attempts to achieve the same objective using zeolite membranes. Pantazidis et al. [206] have evaluated and compared the catalytic performances of catalytic V–Mg–O and Ni membrane reactors in the oxidative dehydrogenation of propane between 300°C and 600°C, using macroporous and mesoporous structures, and a silicalite-1 membrane reactor enclosing a fixed bed of V–Mg–O catalyst. When two reactor configurations—separate feed configuration (oxygen distributor) and co-feed configuration (flow-through contactor)—were tested, a selectivity value four times higher for the former mode was observed. Nevertheless, the best performance was achieved with the inert zeolite-membrane reactor when a separate feeding configuration at high oxygen partial pressures was used (yield to propene 14.6 at 480°C). In a second approach to the same reaction, Julbe et al. [207] used MFI and V-MFI membranes [208] between 550°C and 650°C. The direct addition of a very low vanadium content during the formation of the silica-rich zeolite framework led to stable V-MFI/ $\alpha$ -Al<sub>2</sub>O<sub>3</sub> composite membranes free of macrodefects (>50 nm). The observed activity of the MFI membrane, which should be theoretically inactive, may be related to acidic sites created after aluminum dissolution from the support during the hydrothermal synthesis (high pH) and leading to a H-ZSM-5 membrane. The propene yields were only moderate, but they were better for the V-MFI membrane. In spite of this, the performance of the membrane, in terms of selectivity and yield, when used as an oxygen distributor, was no better than in the flow-through configuration, which the authors attributed to back-mixing and residence time effects. In a later work from the same laboratory [209], several tubular inert membranes (microporous MFI zeolite, mesoporous SiO<sub>2</sub>, and meso-macroporous AlPO<sub>4</sub>) were evaluated in view of their ability to control the O<sub>2</sub> partial pressure in the catalyst side and to limit the back-diffusion of C<sub>3</sub>H<sub>8</sub> and derived products to the O<sub>2</sub>-rich side by application of a transmembrane pressure gradient. The best results were obtained with the low porosity meso-macroporous membrane, in which the viscous flow contribution to permeation provided an increased barrier effect.

Similarly, Mota et al. [210] carried out the selective oxidation of butane to maleic anhydride over VPO mixed oxides-based catalysts enclosed in an MFI membrane. Different feed configurations of the zeolite-membrane reactor were tested to outperform the conventional co-feed configuration. The results achieved were rather similar; however, the authors pointed out the possibility to take advantage of the O<sub>2</sub> distribution, which limits the flammability problems and allows operation with higher butane concentrations than those used in conventional processes.

It seems that zeolite membranes may not be the best choice as catalytic contactors and oxygen distributors to enhance selectivity in oxidative dehydrogenation of propane. This may be due in part to the intrinsic catalytic activity of the zeolite material for this reaction, which probably exerts a nonselective contribution. Therefore, this specific application operates at conditions that do not make use of the most important properties, which are characteristic of zeolite membranes. More efficient approaches for selectivity enhancement can be obtained with zeolite membranes, as shown in the next section.

### 10.6.2.4 Zeolite-Membrane Reactors for Selectivity Enhancement by Control of Reactant Traffic: A Not-So-Classic Application

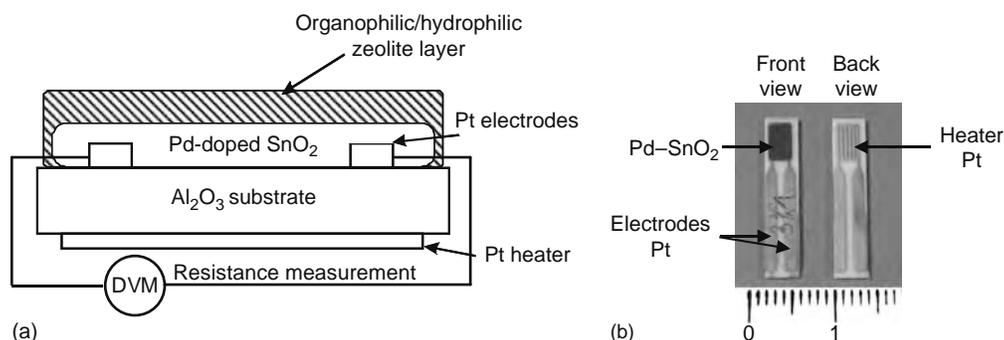

As shown before, secondary reactions represent a common problem in the production of bulk and fine chemicals involving reactions such as oxidation, hydrogenation, alkylation, and halogenation. The well-known kinetic consequences of such successive reactions often require low conversion, reaction control (no transport limitation), and short residence time to achieve acceptable selectivities. Regarding the last issue, in the next section devoted to catalytic zeolite-membrane reactors, the potentiality of this technology for such purposes is demonstrated. However, a more elegant way to overcome this problem is by preventing the product from secondary reactions by taking advantage of the separation properties of microporous membranes. In this section, we are proposing a not-so-classic application for these kinds of membranes that has been scarcely explored up-to-date.

**FIGURE 10.24** Model of the prevention of secondary reactions by single-file diffusion in microporous membranes. (Adapted from Lange, C., Storck, S., Tesche, B., and Maier, W.F., *J. Catal.*, 175, 280, 1998.)

Microporous membranes in general (pore diameter  $<2$  nm) and zeolite membranes in particular have pores whose dimensions are similar to those of many molecules. This means that often molecules cannot pass each other in a restrictive pore medium, and single-file diffusion occurs. Such a molecular queuing (see Figure 10.24) may provide a new scenario for avoiding secondary reactions, i.e., to increase selectivity in consecutive reaction networks with a valuable intermediate product, as demonstrated by Lange et al. [211]. These authors used a non-zeolitic microporous Pt/TiO<sub>2</sub> catalytic membrane supported on an alumina disc to carry out the selective hydrogenation of 2-hexyne and hexadiene at 60°C–120°C. In this case, the hydrocarbon reactant (liquid phase) and the dissolved hydrogen were fed to one side of the catalytic membrane, and forced to permeate through it by using an excess of pressure (0.05–1.5 bar). If the reactants are fed in adequate proportions, under single-file diffusion transport the probability of a new collision of hydrogen with an already semihydrogenated molecule is much lower due to the one-dimensional movement through the membrane brought about by a pressure gradient across the membrane, increasing the yield to selective hydrogenation products. Under these specific conditions, the microporous membranes exhibited hydrogenation activity and selectivity significantly higher than those of comparable batch catalysts. In a mixture of possible reactants, one can also increase the selectivity by opting for the reactant that actually arrives to the catalyst. This was clearly demonstrated some years ago by van der Puil et al. [212,213], who deposited a 0.8–1.3 μm silicalite-1 layer on top of a Pt/TiO<sub>2</sub> catalyst for the competitive hydrogenation of heptene and 3,3-dimethylbut-1-ene at 100°C. Both compounds gave similar conversions when uncoated Pt/TiO<sub>2</sub> catalyst particles were used. However, on the silicalite-1 coated catalyst the conversion of heptane was 37 times faster compared to dimethylbutene due to the selective permeation of the linear compound. A second effect of the silicalite-1 layer was to limit the amount of hydrogen reaching the active layer due to blockage of the hydrogen passage by adsorbed hydrocarbons. This led to an increase in the reaction selectivity toward isomerization products. Similarly, Nishiyama et al. [214] have synthesized a 40 μm silicalite-1 layer on spherical Pt/TiO<sub>2</sub> particles (0.5 mm in diameter) to carry out the hydrogenation of a mixture of 1-hexene and dibranched 3,3-dimethylbut-1-ene. The obtained results indicate the feasibility of the application of catalyst particles coated with a permselective membrane to achieve linear reactant selectivities at molecular level.

This type of approach (reactant filtering) has a tremendous potential in fields such as reactive semiconductor sensors, where the main problem is the lack of selectivity. Figure 10.25a illustrates a typical sensor scheme. The measuring electrodes and the heating resistance are printed on either side of a suitable substrate (i.e., alumina plate). Then, the active layer is screen-printed on top of the electrodes (seen as the obscure area on the front view of the sensor in Figure 10.25b), and after a stabilizing heat treatment, the device is ready for sensing. The sensor material usually contains SnO<sub>2</sub> as the active layer, often doped with Pd, although other base metal oxides and dopants have also been employed. The conductivity of the sensor material changes after exposure to reducing gases, which react with chemisorbed oxygen. With n-type semiconductors such as SnO<sub>2</sub>, adsorbed oxygen immobilizes electrons near the surface of the SnO<sub>2</sub> particles. If a gas, such as a hydrocarbon, reacts with adsorbed oxygen, electrons are released, and the resulting increase in electrical conductivity can be related to the gas-phase concentration of the hydrocarbon. The main problem with existing semiconductor-gas sensors is that they react similarly to a variety of substances. Therefore, they are subject to interference from many other molecules that contribute to the sensor

**FIGURE 10.25** SnO<sub>2</sub> sensors modified with zeolitic filters: (a) schematic representation of the zeolite-coated sensor and (b) (See color insert following page 588.) front and back view of the as-received SnO<sub>2</sub> sensors.

response. As shown in Section 10.6.6.2, Vilaseca et al. [215] were able to strongly increase the selectivity of a SnO<sub>2</sub> sensor by using zeolite films grown on top of the SnO<sub>2</sub> layer to discriminate between the molecules reaching the sensing area.

Recently, Gora et al. [216,217] have proposed the use of zeolite-membrane reactors for hydroisomerization of alkanes. Hydroisomerization of light alkanes is becoming extremely important as an alternative for octane upgrading, and consequently the integration of reaction and separation into one unit by a membrane reactor could offer new and promising industrial possibilities, densifying the process and reducing substantially operating costs. Explorative experiments with C<sub>6</sub> were carried out in a reactor in which linear molecules were separated from monobranched ones on a silicalite-1 membrane before conversion on a Pt-loaded chlorinated alumina catalyst. In this way, the equilibrium was shifted toward the product side, and by feeding only reactants to the catalyst bed, the extent of cracking and coking on the catalyst could be limited. Results of the *n*-hexane hydroisomerization experiments performed showed hexane-2-methyl pentane separation selectivity higher than 20, high hexane conversion (up to 72%), and product selectivity toward dibranched isomers (up to 36%). Hence, the inert zeolite-membrane reactor has an enormous potential in upgrading low octane value hydroisomerization feed streams.

### 10.6.3 CATALYTIC ZEOLITE-MEMBRANE REACTORS

The vast majority of the examples discussed up to now, with some exceptions [182,183,194,207], deal with membrane-assisted reactors in which zeolite membranes do not play any direct role in the catalytic reaction because the catalyst is physically separate from the inert support. However, if the membrane acts as an active contactor, the controlled diffusion of reactants to the catalyst can lead to an engineered catalytic reaction zone. Two main configurations of catalytic membrane reactors can be considered here: (1) the catalyst dispersed or immobilized in an inert zeolite membrane, and (2) an inherently catalytic zeolite membrane. In the former approach, the catalytic and separation functions are engineered in a very compact fashion, whereas for the latter, the zeolite membrane serves as both separator and catalyst. Regardless, the concept can be used in flow-through configuration or with an opposing reactant mode (see Figure 10.22) to improve the access of reactants to the catalyst. In general, the flow-through configuration contactor has been traditionally applied for enzyme-catalyzed reactions, whereas the opposing reactant mode is normally used when the reaction is considerably fast compared to transport resistance.

Relatively, few examples have been found in literature about catalytic zeolite-membrane reactors, and most of them are related with the fine chemicals industry as is shown in the following sections.

#### 10.6.3.1 Catalytic Zeolite-Membrane Reactors for Selectivity Enhancement by Control of Residence Time

A high quality zeolite membrane ideally constitutes a controlled thickness interphase with homogeneous properties. When the membrane has catalytic activity it should be possible, theoretically, to tailor the operating conditions in such a way as to obtain an optimum contact time of the reactants, which render in higher yields to the desired product. This concept has been demonstrated for *i*-butene oligomerization in gas phase [218] and methanol reaction into olefins [219]. In the former work, *i*-butene oligomerization was carried out at 323–423 K in a flow-through  $\beta$ -zeolite film prepared on a porous  $\alpha$ -alumina tubular support. The process gives not only *i*-octene from *i*-butene but also unwanted C<sub>12</sub> and C<sub>16</sub> products. By controlling the residence time of the reactants in the membrane pores, the authors not only increased the *i*-octene selectivity and yield with respect to the homologous catalytic fixed bed reactor but also reduced the deactivation of the catalytic membrane. As a result, while deactivation of a fixed bed reactor (containing the same zeolite as a catalyst) occurred in 4 h, the authors were able to operate their membrane reactor for nearly 170 h without loss of activity. This suggests that the same mechanism that minimized the formation of C<sub>12</sub> and C<sub>16</sub> products also prevented the oligomerization processes giving rise to coke precursors.

Using a similar approach, Masuda et al. [219] employed a ZSM-5 zeolite membrane in a flow-through configuration for the methanol-to-olefins process. As in the previous work, permeating molecules would ideally have a uniform residence time

within the catalytic zeolite layer, while a wide distribution of residence times would exist in fixed bed and fluidized bed reactors. In this reacting system, methanol is first converted to dimethylether, then to olefins. However, further reaction produced paraffins and aromatics, which in this case are the unwanted final products. By optimizing the match between diffusion rate and chemical reaction rate, the authors were able to produce olefins with high selectivity (about 80%–90%) from methanol at high conversions (60%–98%).

Another way to control the residence time of valuable intermediate products within the reactor is to use a selective membrane to remove them from the reaction environment as they are produced before they can react further in consecutive reactions. Therefore, it is a classical example of an IMR in which a considerable increase in the yield to the desired product can be obtained, provided that the membrane is sufficiently selective to the intermediate product under reaction conditions. Regarding this approach, Piera et al. [220] solved the selectivity problem already discussed in the oligomerization of *i*-butene by removing selectively the *i*-octene formed using an MFI zeolite membrane surrounding a fixed bed of acid resin catalyst. In liquid-phase experiments (3–25 bar and 20°C–80°C) with different mixtures it was shown that the membrane was able to selectively separate *i*-octene from the other components present in the mixture. This reaction system is not equilibrium limited under the conditions used. However, the simulations carried out showed that the use of a zeolite-membrane reactor could result, not only in higher reaction selectivity but also in a higher conversion, due to the increase of the residence time of *i*-butene in the reactor as products are selectively removed. The experiments confirmed these predictions, and the zeolite-membrane reactor gave *i*-octene yields that were up to 27% higher than those found in a fixed bed reactor under comparable conditions.

Degradation of volatile organic compounds (VOCs) has also been tested on catalytic zeolite-membrane reactors. Maira et al. [221] have studied the photocatalytic oxidation (PCO) of an airborne VOC pollutants such as trichloroethylene. These authors prepared a hybrid membrane-catalyst by secondary growth of silicalite-1 onto a porous stainless steel plate followed by coating with a nanostructured anatase TiO<sub>2</sub> suspension. The reactor could be operated in a flow-through or in a parallel flow configuration, and it was found that both the trichloroethylene conversion and the selectivity to CO<sub>2</sub> were significantly higher in the flow-through configuration. The authors explained the higher selectivity toward deep oxidation products as a result of the molecular sieving function of the membrane toward the smaller products from total mineralization. In this way, the permeation of larger pollutant molecules would be delayed, allowing for longer residence times and higher conversion. In a recent publication, Aguado et al. [222] proposed the use of a Pt-ZSM-5 membrane reactor for the combustion of *n*-hexane, present at low concentrations in air (1000 ppmv), using an opposing reactant mode configuration. The role of the zeolite is to adsorb and concentrate the VOC on the retentate side, thereby facilitating reaction; whereas the presence of air as sweep gas (which in this case is also a reactant) facilitates diffusion toward the permeate side where the catalyst is preferentially located. The investigation deals mainly with the relationship between the permeation properties of the zeolite membrane and its performance as a reactor. Unlike the previous cases, here, the control of the residence time is modulated by the concentration of intercrystalline defects within the zeolite layer. Thus, while it could be expected that membrane reactor performance would increase with membrane quality, this does not seem to be the case. Apparently, in membranes with a moderately high value of the SF<sub>6</sub> permeance, the presence of intercrystalline voids facilitates the penetration of reactant molecules into the membrane and their contact with the catalyst. As a result, nearly complete combustion of *n*-hexane is achieved at 210°C. On the other hand, for membranes with a low SF<sub>6</sub> permeance, diffusion takes place essentially through the zeolite-pore network. This is a slower process in comparison with the reaction kinetics, and given the residence time of the molecules in the retentate side, only a fraction of the molecules actually have the chance to come into contact with the catalyst.

Finally, Hasegawa et al., in a series of works [223–226] dealing with the oxidation of CO when it is present at low concentrations in a hydrogen atmosphere (a very important subject for the practical implementation of fuel cells), have demonstrated the benefits of a zeolite-membrane reactor working in an opposing reactant mode configuration. In the first of these works [223], the authors used Pt-loaded Y-type zeolite membranes, prepared by secondary growth over tubular supports followed by ion exchange, as interphase contactor for a H<sub>2</sub> stream containing 10<sup>4</sup> ppm of CO at temperatures of 200°C–250°C. The residence time of H<sub>2</sub> crossing the membrane was too short to react with O<sub>2</sub>, and the residence time of CO was in the range of values used for selective CO oxidation in a conventional packed bed reactor; thus the reaction of CO was favored. In this way, 1000 ppm of CO in the feed could be reduced to less than 8 ppm at the permeate side. Other metals (Ru, Rh, Ni, Cu, Ag) were also exchanged on zeolite Y [188], but the best results were obtained with the Pt/zeolite Y membrane.

Apart from this, it is worthwhile to emphasize the potential application of zeolite-based membranes as electrolytes for direct methanol fuel cells (DMFCs) due to their proton conduction properties (4227). Existing Nafion-based proton exchange membrane (PEM) fuel cells still face significant challenges related to CO poisoning of the catalyst at the anode, water management, and slow kinetics. Increasing the operating temperature significantly above 100°C would help to solve these problems but would decrease the hydration needed for proton conduction. Zeolite particles seem to be ideal candidates as polymer fillers on account of their hydrophilicity and proton-transport capabilities [228–231]. Although the proton transport across the zeolite membranes tested thus far is still low compared to PEMs employed in fuel cells, transport in zeolites can be optimized by increasing the number of proton exchange sites on the zeolite, an area where work is still lacking. DMFCs add a further constraint: methanol crossover must be avoided as it reduces both the cell efficiency as well as the efficiency of fuel utilization. Methanol leaking is a serious problem for current Nafion membranes, which are good conductors but poor methanol

barriers. Two main alternatives seem possible at this point. On the one hand, Nafion-zeolite membranes could be prepared [230,232], with the aim of maintaining the good proton-conducting properties of Nafion, and at the same time, increasing methanol rejection as the proportion of zeolite filler increases. On the other hand, composite polymer-zeolite membranes could be prepared, where the polymer material is chosen to achieve low methanol diffusion [228]. Libby et al. [231] added a further possibility related to tailoring the properties of the polymer by thermal treatment. After treating their membrane at 150°C for 27 h, the permeability of the PVA phase has decreased enough so that their PVA/mordenite membrane showed a 20-fold improvement in selectivity (defined as the ratio between proton conductivity and methanol permeability) over Nafion. Recent results in high temperature methanol fuel cells 130°C–150°C, published by Baglio et al. [232] over composite Nafion membranes containing mordenite, show improved electrochemical behavior at 140°C over the recast Nafion membrane. The power density achieved (390 mW/cm<sup>2</sup>) is interpreted in light of surface acid–base properties of the zeolitic filler in the composite membrane.

### 10.6.3.2 Catalytic Zeolite-Membrane Reactors in the Fine Chemicals Industry

Membrane technology is a well-established technology for the immobilization of enzymes [233] since Degussa [234] introduced a continuous acylase process employing an enzyme-membrane reactor for the enantiomeric production of pure L-amino acids in 1981. Polymer membranes configured into hollow-fiber modules are, by far, the most widely used membrane where the enzyme is held back by the low cutoff of the membrane.

Matsui et al. [235,236] have recently used zeolites with a higher Si/Al ratio (i.e., Na–BEA) for the purification of nucleic acids and proteins due to the electrostatic and hydrophobic interactions between biopolymers and zeolites. In addition, the activity and structure of the proteins are preserved even under denaturing conditions, thus emerging as promising materials for biochemical and biotechnological applications.

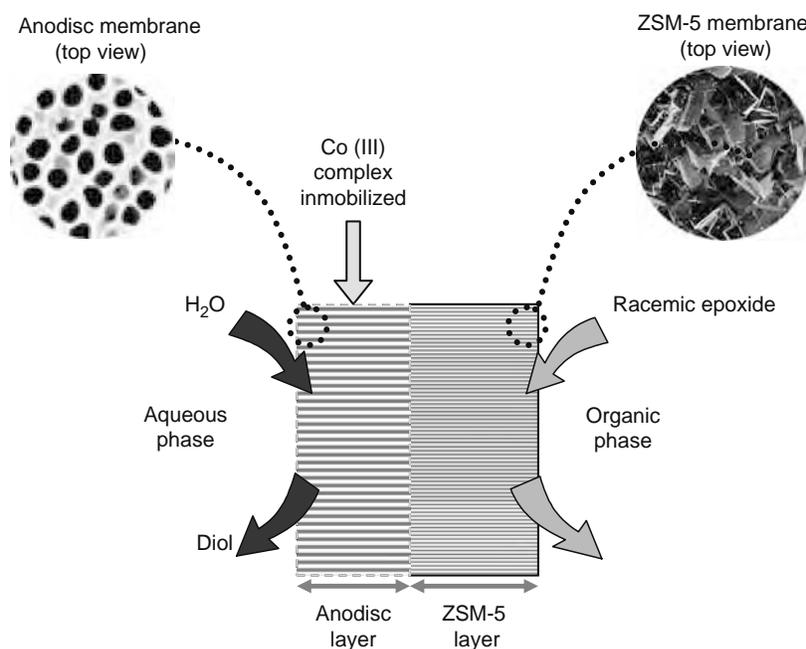

Based on these observations, Wang and Caruso [237] have described an effective method for the fabrication of robust zeolitic membranes with three-dimensional interconnected macroporous (1.2 μm in diameter) structures from mesoporous silica spheres previously seeded with silicalite-1 nanoparticles subjected to a conventional hydrothermal treatment. Subsequently, the zeolite membrane modification via the layer-by-layer electrostatic assembly of polyelectrolytes and catalase on the 3D macroporous structure results in a biomacromolecule-functionalized macroporous zeolitic membrane bioreactor suitable for biocatalysts investigations. The enzyme-modified membranes exhibit enhanced reaction stability and also display enzyme activities (for H<sub>2</sub>O<sub>2</sub> decomposition) three orders of magnitude higher than their nonporous planar film counterparts assembled on silica substrates. Therefore, the potential of such structures as bioreactors is enormous.

Zeolite membranes are amenable by surface modification with a variety of chemical functional groups using simple silane chemistry, which may provide alternative surface chemistry pathways for enzyme immobilization. In this context, Shukla et al. [238] have recently used a chemically modified zeolite–clay composite membrane for the immobilization of porcine lipase using glutaraldehyde to provide a chemical linkage between the enzyme and the membrane. The effects of pH, temperature, and solvent on the performance of such biphasic zeolite-membrane reactors have been evaluated in the hydrolysis of olive oil to fatty acids.

Membrane technology developed for enzymatic reactions is now being introduced to homogeneous organic catalysis with the aim of minimizing the amount of catalyst required per kilogram of product produced. For a large number of reactions, homogenous catalysts show better activity and (enantio) selectivity compared to heterogeneous catalysts. There are, however, two main disadvantages: one caused by the organic solvent used for the reaction medium and the difficult separation of the catalyst from the products. With respect to the first shortcoming, it is generally thought that the use of supercritical solvents (SCFs) [239] could eliminate environmental concerns pertaining to VOC dissemination and at the same time obtain high concentrations of reactants, products, and catalyst due to the solvent properties of SCFs. Regarding the second drawback, one of the most common techniques for catalyst separation is running the reaction mixture through a fixed bed reactor, with the catalyst covalently bounded via a suitable functional linker or tether to an insoluble polymer as support [240].

In particular, for the synthesis of optically pure chemicals, several immobilization techniques have been shown to give stable and active chiral heterogeneous catalysts. A further step has been carried out by Choi et al. [241] who immobilized chiral Co(III) complexes on ZSM-5/Anodisc membranes for the hydrolytic kinetic resolution of terminal epoxides. The salen catalyst, loaded into the macroporous matrix of Anodisc by impregnation under vacuum, must exit near the interface of ZSM-5 film to contact with both biphasic reactants such as epoxides and water. Furthermore, the loading of chiral catalyst remains constant during reaction because it cannot diffuse into the pore channel of ZSM-5 crystals and is insoluble in water. The catalytic composite zeolite membrane obtained acts as liquid–liquid contactor which combines the chemical reaction with the continuous extraction of products simultaneously (see Figure 10.26): the epoxide remained in the organic phase and the hydrophilic diols could diffuse into the aqueous phase across the ZSM-5 film layer. As a result, high enantioselectivity and recyclability are achieved in the asymmetric hydrolysis of terminal and mesoepoxides at room temperature.

The same concept was proposed by Langhendries et al. [242] for the selective liquid-phase hydrocarbon oxidation. In this reactor configuration, the organic substrate (cyclohexane and *n*-dodecane) and the aqueous oxidant phase

**FIGURE 10.26** (See color insert following page 588.) ZSM-5/Anodisc membrane system used in the enantioselective asymmetric hydrolysis of racemic epoxides. (Adapted from Choi, S.D. and Kim, G.J., *Catal. Lett.*, 92, 35, 2004.)

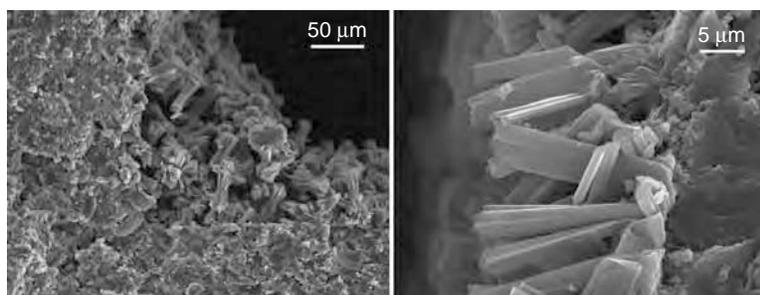

(*t*-butyl-hydroperoxide) are contacted through a catalytic composite zeolite-membrane; where alcohol and ketone oxidation products are recovered depending on their solubility in both phases. The catalytic composite zeolite-membrane consisted of a NaY-zeolite-encapsulated iron-phtalocyanine complex embedded in a hydrophobic poly(dimethylsiloxane) (PDMS) polymer membrane. In a similar way, Wu et al. [243] have studied the *n*-hexane oxifunctionalization by hydrogen peroxide using a titanium silicalite-1 zeolite/PDMS composite membrane as a liquid-vapor interphase contactor. The value of this approach, is that it eliminates the necessity for a solvent, and, therefore, solves the problem of excess peroxide at the active sites and often increases reaction rates by optimising the substrate/oxidant ratio at the catalyst surface, which has been further demonstrated by different authors [244,245].

Even so, undesirable effects, such as deactivation and loss of selectivity for heterogeneous catalysts, are unavoidable for some specific reactions. Hence, separation of homogeneous chemical catalysts by membrane retention or immobilization is emerging as a new application field, which, in fact, demands supports that combine thermal and mechanical stability with chemical resistance under reactive conditions. As a first approach, zeolite membranes can act as molecular filters able to retain the homogeneous catalyst, i.e., as a simple separator. MFI zeolite membranes have been applied by Turlán et al. [246] in the Heck reaction to allow the permeation of a product (4-cyanomethylcinnamate) while retaining the homogeneous catalyst employed ( $[\text{Pd}(\mu\text{-Cl})(\text{PPh}_3)_2]_2(\text{BF}_4)_2$ ), which has a larger size than the pores of the MFI membranes used. This approach is also being pursued with polymeric membranes that are more flexible in terms of the species that can be targeted, but experience stronger limitations in terms of temperature and solvent resistance. Smet et al. [247] combined nanofiltration with homogeneous catalysis to obtain the best possible reaction rates, chemoselectivities, and enantioselectivities in a continuous operation mode while recycling the catalyst. More recently, silicalite-1 membranes have been successfully employed for catalyst retention ( $[\text{Pd}(\mu\text{-Cl})(\text{Ph}_2\text{P}(\text{CH}_2)_4\text{PPh}_2)](\text{CF}_3\text{SO}_3)_2$ ) from postcatalytic reaction mixtures by the molecular sieving effect in the Diels-Alder reaction [248].

To circumvent simultaneously the two major drawbacks associated with homogeneous catalysis already quoted, Goetheer et al. [249] have proposed a membrane reactor for homogeneous catalysis in supercritical carbon dioxide with in situ catalyst separation. In particular, a membrane reactor working in a flow-through configuration has been tested for the hydrogenation of 1-butene to *n*-butane with a fluorine derivative of Wilkinson's catalyst in  $\text{SCCO}_2$  at 353K and 20 MPa. The microporous silica membrane employed (0.5–0.8 nm as pore diameter) was able to retain completely the catalyst (2–4 nm) under reaction conditions which renders turnover frequencies significantly higher than those obtained using an organic solvent. However, the same concept could be perfectly translated to zeolite membranes with suitable pore diameters and relative low affinity toward carbon dioxide.

#### 10.6.4 ALTERNATIVE SUPPORTS AND CONFIGURATIONS FOR ZEOLITE-MEMBRANE REACTORS

In addition to porous ceramic and stainless steel plates and tubes commonly employed as supports of zeolite membranes and films, a wide variety of alternative supports have been used. Among these are steel [250], ceramic [251,252] monoliths

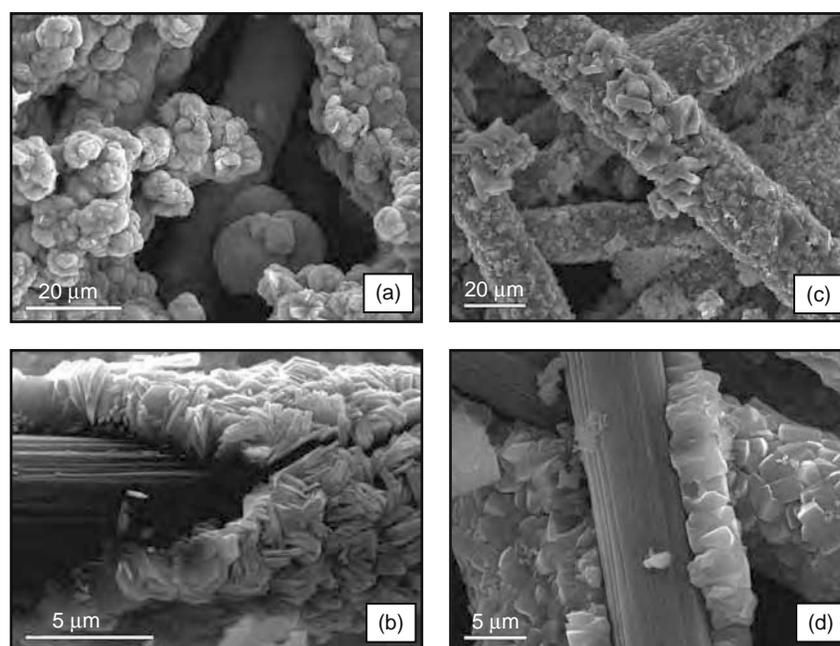

**FIGURE 10.27** Left: cross section of a mordenite film prepared on a cordierite monolith. Right: detail of the film.

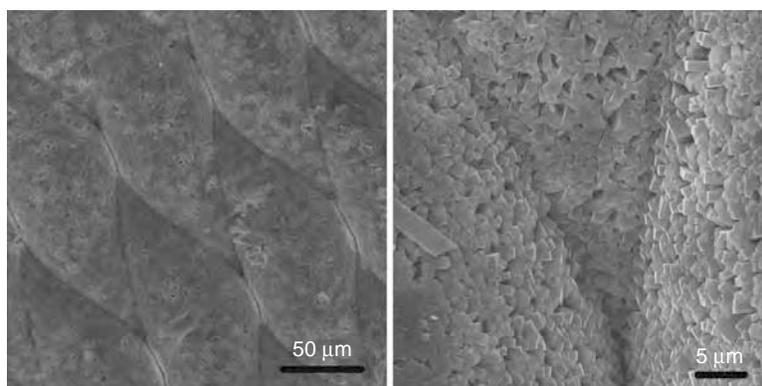

(see Figure 10.27) (also shaped as wheels or rotors [253]), stainless steel grids [254,255], wire gauze packings [256], glass fibers [257–258], nonporous ceramic [259], metal [260] plates, and glass and steel beads [261]. Figure 10.28 shows SEM images of ETS-10 and umbite titanosilicate-based membranes supported on commercial carbon Toray paper commonly used as porous electrode for fuel cell applications. The as prepared membrane-electrode assemblies (MEAs) were synthesized by secondary growth following the procedure described by Lin et al. [27].

While, in general, the investigations discussed in this section do not belong to the field of zeolite-membrane reactors, they are mentioned here because they provide interesting clues and ideas for further development of existing systems.

Monoliths have been proposed for different end-of-pipe catalytic processes, on account of their flexibility of operation, good tolerance to the presence of dust, low pressure drop, reasonable commercial costs, and relatively easy scale-up [262]. An additional advantage in zeolite-coated monoliths is the fact that they can be prepared binderless and they do not require a washcoat support layer (an important feature for increasing the catalyst loading over the monolith). Monolithic structures such as ZSM-5 prepared on cordierite by liquid-phase hydrothermal synthesis [251,263,264], or by solid-state in situ crystallization [265,266], are mainly oriented toward automotive applications. Particularly remarkable are the results of Ulla et al. [251,252] where loadings up to about 30% and 50% by weight for ZSM-5 and MOR, respectively, have been reported. After preparation, the zeolite layers can be ion exchanged to modify their activity. Thus, Basaldella et al. [263] prepared Cu-ZSM-5 layers, which are catalytically active for the selective reduction of NO<sub>x</sub>. ZSM-5 coatings have also been prepared on mullite honeycomb supports [267], ceramic slabs [259], and foams [268]. BEA coatings (loadings up to 9 wt%) have been prepared by dipping monolithic and wire gauze packings in a BEA slurry. The resulting structures showed high activity for the acylation of

**FIGURE 10.28** Scanning electron microscopy (SEM) images of (a, b) Umbite and (c, d) ETS-10 supported on carbon Toray paper. (From Aused, M.P., Urbiztondo, M.A., Mallada, R., Pina, M.P., and Santamaría, J., Synthesis of proton conducting membranes for direct methanol fuel cells (DMFCs). Books of abstracts of the OSSEP Final Workshop, Tenerife, 2004, pp. 90–91.)

**FIGURE 10.29** Scanning electron microscopy (SEM) images of silicalite membrane on stainless steel grid support.

aromatics [254]. Similarly, a structured catalytic bed made of ZSM-5 coatings grown by hydrothermal synthesis on stainless steel grids has been used for the hydroxylation of benzene [254].

Zeolite monoliths have been useful for such applications as rotatory adsorbers for use as dehumidifiers and desiccant cooling processes [253] or in VOC treatment systems [269]. Alumina-coated silicon carbide monoliths have also been employed as supports for B-ZSM-5 membranes [270] providing a larger surface area per unit volume, compared to traditional membrane supports. With these membranes, these authors have reported *n*/*i*-butane and H<sub>2</sub>/*i*-butane separation selectivities of 35 and 77, respectively [85]. Also, silicalite-1 membranes supported on stainless steel grids (Figure 10.29) have shown a good performance in the separation of *n*/*i*-butane mixtures, with separation factors as high as 53 at 63°C [255].

Finally, zeolite nanoparticles have been used as building blocks to construct hierarchical self-standing porous structures. For example, multilayers of colloidal zeolite crystals have been coated on polystyrene beads with a size of less than 10 μm [271,272]. Also, silicalite-1 membranes with a thickness ranging from 20 to several millimeters and controlled mesoporosity [273] have been synthesized by the self-assembly of zeolite nanocrystals followed by high-pressure compression and controlled secondary crystal growth via microwave heating. These structures could be useful for separation and catalysis applications.

### 10.6.5 INDUSTRIAL APPLICATIONS OF ZEOLITE-MEMBRANE REACTORS

Today, annual market membrane of ca. U.S.  $\$4.5 \times 10^9$  for membranes and membrane modules (mostly polymeric ones) indicates that separation processes seem to be the largest application field, whereas membrane reactors are just on the verge of being considered as a competitive tool [274].

Weisz [275] defined a trade-off range for the operation of catalytic reactors in industry based on the space-time yield (STY) which should be centered around 1–10 mol/s m<sup>3</sup>. This figure is a balance between reactor size and mass and heat transfer limitations. The STY value of catalytic reactors should be compared to the permeability of zeolite membranes to draw conclusions about the feasibility of using zeolite-membrane reactors for industrial applications. Boudart [276] has suggested the use of analysis of orders of magnitude to screen-proposed membrane reactors for practicality under industrial conditions based on the areal time yield (ATY), which is in fact the same as the permeation flux. The feasibility of membrane reactors can be determined by dividing the value for STY by the value for ATY, thus obtaining the area to volume ratio of the catalytic membrane reactor. Realistic values for industrial applications are around 10–100 m<sup>-1</sup>; therefore, based on published permeation data, zeolite-membrane reactors would be a feasible technology for some applications.

Although the enormous potential payoff of this technology has been largely demonstrated at the laboratory scale, the technological gap that still has to be filled to achieve industrial practice is rather clear. Caro et al. [3] pointed out that the challenges for industrial application are in the membrane development and lack of module reliability under extreme temperature cycling. Chiang and Chao [167] noted the need to reduce membrane thickness and to increase the membrane surface to volume ratio, something that could be achieved by the use of alternative supports (monoliths, hollow fibers, metal gauze) as shown in the previous section. A step in this direction is the synthesis of zeolite membrane layers on the inner side of alumina capillaries (1.9 mm inside diameter) recently reported by Richter et al. [277]. Noack et al. [278] stressed the need to develop membranes with larger areas that can be prepared with satisfactory reproducibility. By systematically varying the synthesis conditions, these authors were able to prepare a series of silicalite-1 tubular membranes in which the proportion of high quality membranes was 70%. Recently, Pina et al. [33] have synthesized zeolite NaA membranes on the external surface of  $\alpha$ -alumina tubular supports using a semicontinuous system in which fresh gel is periodically supplied to the synthesis vessel. Compared to traditional batch methods, the procedure developed in this work provides a better control of the synthesis and crystallization conditions and is easier to implement at an industrial scale. Morooka and Kusakabe [279], among others, raised

the issue of durability under elevated pressures and temperatures, stability in steam-containing atmospheres, and membrane regeneration.

In spite of all these hurdles, there are already industrial-scale applications of zeolite membranes for solvent dehydration [106] by pervaporation plants using tubular zeolite A membranes with 0.0275 m<sup>2</sup> of permeation area each (see Section 10.2.3). Li et al. [280] have prepared large area (0.0260 m<sup>2</sup>) ZSM-5 membranes on tubular  $\alpha$ -alumina supports. This work is also interesting from the industrial point of view because the authors used inexpensive *n*-butylamine as template. Indeed, the cost required for industrial modules, on a general basis, is still far from clear. However, it must be noted that most of the costs can be ascribed to the module, and only 10%–20% to the membrane itself [3]. This underlines again the importance of preparation of zeolite membranes on cheaper, alternative supports that can also pack more area per unit volume.

### 10.6.6 NEW APPLICATIONS OF ZEOLITE-MEMBRANE REACTORS: MICROCHEMICAL SYSTEMS

The specificity, adsorption, and catalytic properties, besides the possibility of zeolite pores to host different ions, atoms, molecules, and clusters, have opened up numerous opportunities as advanced nanomaterials [227,281].

The last few years have seen the proposal of new applications for zeolite membranes and coatings involving microchemical systems (microreactors, membrane microseparators, and sensors) in which the characteristic length is measured in microns [6]. Commercial applications of zeolite membranes do not necessarily imply dimensions of many square meters of permeation area in a single unit. Actually, scaling-down should allow preparing defect-free zeolite membranes (eventually single-crystal membranes) over an endless variety of supports, and combinations with other materials at the microscale that would have a higher chance of tolerating the inherent thermal and mechanical stresses produced during thermal cycling (a very important subject for industrial implementation of this technology see Section 10.6.5).

Ideally, microscale systems will be made of smart nanostructured materials capable of very specific interactions with molecules, ions, and atoms. Indeed, the advances in microstructured devices for chemical reactions and the benefits already demonstrated have been impressive [282,283]. Some of these microdevices could integrate what Gavriilidis et al. [284] called novel microengineered structures, capable of performing many of the standard operations of interest to chemical systems. Thus, for instance, the *lab-on-a-chip* represents an increasingly familiar concept to express the miniaturization of chemical, biological, and biomechanical analyses [285], and can be envisaged as a scaled-down analog of a chemical processing plant in which a drastic reduction of reactants and energy consumption is achieved.

One of the keys to the success of such microdevices is the selectivity of the reaction and separation steps and their integration for a given process. Regarding the former requirement, nanoporous interfaces of zeolites and related materials emerge as excellent candidates for these kinds of devices. Tsapatsis [286] has highlighted some of the potential contributions of molecular sieving technology to the nanotechnology field, and remarked the need for fundamental advances in understanding and controlling the preparation of these materials and predicting their properties. These advances are necessary to achieve a degree of structural perfection that is not required by their current technological use but will be needed in micro- and nano-device applications.

#### 10.6.6.1 Zeolite-Based Microreactors and Microseparators

The combination of microreactor and zeolite growth concepts rapidly led to zeolite coatings on microreactors. Thus, Rebrow et al. [287] coated 500  $\mu\text{m}$  channels on a stainless steel plate with ZSM-5 crystals and used the resulting microreactor in the selective catalytic reduction of NO with ammonia, attaining higher reaction rates in comparison with the conventional pelletized catalyst. Wan et al. [288] also deposited zeolite coatings in silicon–glass microchannels fabricated by the patterning and etching of a Si wafer. In this case 5  $\mu\text{m}$  thick TS-1 zeolite films, made up of intergrown 3  $\mu\text{m}$  zeolite crystal grains, were supported on 500  $\mu\text{m}$  wide and 250  $\mu\text{m}$  deep microchannel reactors. The authors tested these microreactors in the epoxidation of 1-pentene with hydrogen peroxide at 298 K in a continuous flow, even though irreversible deactivation was observed due to leaching of framework titanium.

Zeolite micromembranes also would be able to perform the separation and reaction operations of standard zeolite membranes, while providing the following advantages: (1) easy integration, at the microscopic level, of reaction and separation, (2) excellent temperature control, (3) possible higher selectivity and conversion compared to conventional reactor, (4) intrinsic safety, and (5) easier scale-up in a highly compact format. Miniaturization also benefits membrane separation by improving mass and heat transfer rates and by providing a large surface/volume ratio (i.e., 3000 m<sup>2</sup>/m<sup>3</sup>) leading to a more efficient and compact separation unit.

The benefits of the use of micromembranes for the selective removal of one or more products during reaction have been demonstrated for equilibrium-limited reactions [289]. For example, the performance of hydrophilic ZSM-5 and NaA membranes over multichannel microreactors prepared from electro-discharge micromachining of commercial porous stainless steel plates was studied by Yeung et al. in the Knoevenagel condensation [290,291] and aniline oxidation to azoxybenzene [292]. For such kind of reactions, the zeolite micromembrane role consists of the selective removal of water, which indeed yields higher conversions, better product purity, and a reduction in catalyst deactivation in comparison to the traditional packed bed reactor.

A different approach to fabricate a zeolite-based microreactor has been recently proposed by Mateo et al. [293]. These authors fabricated an array of free-standing micromembranes involving laser perforation of a thin stainless steel plate to create microholes (30–70  $\mu\text{m}$  in diameter and 75  $\mu\text{m}$  depth) that were subsequently covered by silicalite-1 layers using hydrothermal synthesis by secondary growth. Patterned structures can also be created by covalent bonding to a previously printed structure, as demonstrated by Ha et al. [294]. These authors have extensively investigated the organization of nano- and microcrystalline zeolite particles into uniformly aligned two- (2D) and three-dimensional (3D) multicrystal arrays on various substrates (platinum, gold, glass plates and fibers, silica, alumina, and vegetable fibers) by inducing large numbers of molecular linkages between organic functional groups tethered to the surfaces of both zeolites and substrates. The scope of application of such monolayers assemblies is particularly attractive for applications of zeolites as advanced nanomaterials [281].

The methods for manufacturing of zeolite-based microreactors and microseparators also use traditional semiconductor fabrication procedures. Jansen and van Rosmalen [295] were among the first to describe the growth of continuous zeolite film on silicon wafer. Some years ago den Exter et al. [296] reported the preparation of silicalite-1 oriented monolayers on silicon wafers subsequently transformed, by selective etching procedures, into unsupported thin zeolite layers. Also, Schoeman et al. [297] studied the optimal conditions for the growth of silicalite-1 films on silicon wafers with thicknesses in the range of 180 nm to 1  $\mu\text{m}$ . Today, semiconductor fabrication technology can be considered an established technique, which allows the manufacturing of a range of microelectromechanical systems (MEMS). Yeung and coworkers have described several strategies for incorporating zeolites within the architectural design of microreactors and microseparators. These authors have demonstrated that microelectronic fabrication technology could readily be adapted to synthesize miniature membrane microseparators containing MFI-type zeolite films prepared by secondary growth [298,299].

#### 10.6.6.2 Zeolite-Based Microsensors

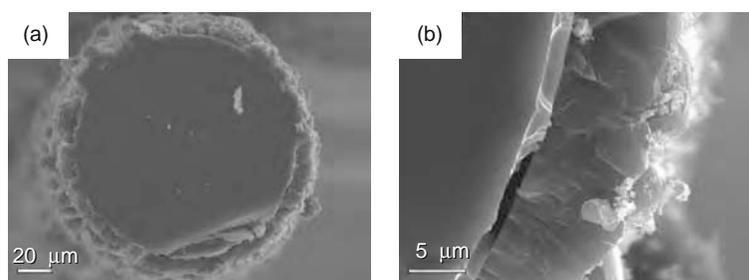

The development of stand-alone devices for monitoring the concentration of selected chemical species in complex samples (or in different environments) has been a major goal in analytical science for several decades. Indeed, chemical microsensors play an increasing role in the areas of environmental monitoring and industrial processing. With the aim of increasing sensitivity and selectivity, zeolites have been used on a variety of chemical sensors, both reactive and nonreactive. Moreover, as a sensing layer, zeolites are very favorable due to their additional high thermal stability and chemical resistance. Thus, zeolites have been employed to improve the surface of conventional chemical electrodes to increase their electroanalytical performance [300], or to conform different types of zeolite-based chemical sensors, as shown below.

Chemical microsensors, having combined molecular sieving effects and selective surface interactions and consisting of zeolite-composite thin films located on the active areas of piezoelectric sensor devices (quartz crystal microbalances, QCMs), have been developed by several authors. The regular micropores of the zeolitic material were found to effectively control molecular access to the device allowing it to sense ethanol (using zeolite MFI, [301]), humidity (using zeolite LTA and BEA, [302]), and NO, SO<sub>2</sub>, and water (using zeolite A, silicalite-1, and sodalite [303,304]). These works demonstrate how the response of zeolite-based piezoelectric sensors can be controlled by the zeolite structure and composition.

Surface acoustic wave (SAW) devices, consisting of a single-crystal quartz substrate with interdigital transducers, can also operate as highly sensitive piezoelectric balances that respond to small fractions of gas adsorption on a single-crystal monolayer via frequency changes of an oscillator circuit. The application of zeolite coatings (H-ZSM-5, zeolite Y, chabazite, and zeolite A) on SAW devices was first applied by Bein et al. [305,306] for humidity and vapor sensing (methanol, ethanol, propanol, isooctane, pyridine, and perfluorotributylamine). These authors found out that selectivity can be enhanced by tailoring the surface and by means of interfacial interactions of zeolite coatings with molecular layers of silane coupling agents [307].

Cantilevers used as nanoscale sensors for AFM have recently been extended beyond those of surface-imaging tools. Similar to QCMs, cantilever-based sensors can also be configured to work as a tiny microbalance in which a resonance frequency analysis can be used to determine mass loading. Standard cantilevers are theoretically capable of detecting a minimum mass loading of 50 fg enabling short response time (milliseconds). Although cantilever exhibits high sensitivity, but, to recognize different specific materials, the improvement of the sensor selectivity becomes a critical factor. For this purpose, attaching zeolite crystals to them further increases their detection sensitivity toward the adsorbed compound while maintaining their micron scale. On the basis of this concept, ZSM-5 crystals (around 500 ng) have been chemically anchored for humidity [307,308] and freon-12 [309] sensing purposes, achieving a satisfactory performance in determining mass loadings at the nanogram scale. Moreover, an array of such devices has been fabricated [308] to conduct complex analysis of vapors by using various microporous materials attached to the sensors.

Optical sensors are among the most important types of chemical sensors that have been produced in the recent past for the continuous and real-time monitoring of diverse analytes [310]. A wide variety of favorable properties for chromophores embedded in inorganic molecular sieves can be expected based on their peculiar host–guest interactions, although they are still at the beginning of their development. Indeed, molecular-sieve encapsulated dye molecules are currently attracting increasing attention with respect to new photonic devices and optical sensor applications [311,312] due to an increased light

**FIGURE 10.30** Scanning electron microscopy (SEM) images of cross section of a commercial optical fiber coated with a NaA zeolite thick layer: (a) total cross section and (b) magnification view of the NaA zeolite layer. (From López, J., Pina, M.P., Coronas, J., Pelayo, J., and Santamaría, J., A novel optical device for gas sensor applications based on zeolitic materials. Books of abstracts of the 1st NanoSpain Workshop, San Sebastian, 2004.)

durability, migration stability, and photodegradation resistance (up to 2 orders of magnitude) with respect to their organic counterparts.

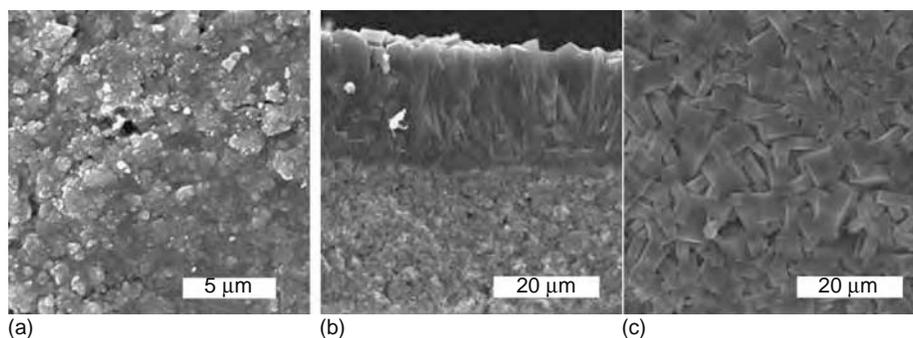

Brühwiler and Calzaferri [313] have recently reviewed the different organization stages for dye-zeolite systems ranging from the arrangement of the dyes in the zeolite channels to the specific adsorption of molecules at the channel entrances, and subsequently, to the coupling of the dye-zeolite crystals to an external device. However, the majority of publications up-to-date in the field of optical gas sensors deal with the first level of molecular assembling. For instance, the encapsulation of the solvatochromic dye Nile red inside the pores of dealuminated zeolite Y by “ship in a bottle” synthesis has been investigated by Meinershagen et al. [314] for optical sensing of acetone and ethanol using spectral absorbance in the UV–VIS range. Taking advantages of the luminescence properties of rhodamine dyes, covalently anchored at the walls of mesoporous Si-MCM-41, Ganschow et al. [315] have developed a SO<sub>2</sub> optical sensor using a glass carrier to overcome the disadvantages of the powdered state. Many research efforts are focused on integrated optical sensors development, in particular toward optical fiber sensors operating at standard telecommunication wavelengths [316]. Many papers have recently been published concerning NaY, LiY, and BaY zeolite crystals coating quartz fibers using TEOS as a binding agent [285,286] for asymmetric photoreactions and also for sensing aromatic molecules (naphthalene) by means of their phosphorescence. As an example, Figure 10.30 shows SEM micrographs of zeolite NaA films, 7 μm thick, prepared by secondary growth [35] over the external surface of commercial optical fibers previously activated for being used as fiber optic evanescent-field gas sensors using absorption in the near infrared.

Since the adsorption of a gas is able to modify the dielectric constant of zeolites, chemical sensors based on interdigital capacitors (IDCs) using zeolites layers as sensitive coatings offer a wide field of applications depending on the type, modification, and working temperature of the coated IDC sensor.

Thus, zeolite-coated IDCs have been tested for sensing *n*-butane [317] and also, NH<sub>3</sub>, NO, and CO [318,319] on Na–Y and NaPtY zeolite-based sensors at temperatures high enough to where chemical reactions may also occur (above 200°C). The response time is of the order of seconds and the cross-sensitivity to water is small at high temperatures, at which no water condensation occurs in the zeolite-pore system. Under certain conditions, selectivity of these reactive chemical sensors is remarkable. Thus, the detection of 10 ppm of *n*-butane with a NaPtY interdigitated capacitor with no response to CO and H<sub>2</sub> has been reported [318]. Similarly, Moos et al. [320] described a ZSM-5 based capacitor sensor with on-chip heating for temperatures up to 450°C capable of detecting NH<sub>3</sub> with no cross-sensitivity to CO, hydrocarbons, and O<sub>2</sub>.

Reactive chemical sensors and their problems with selectivity have been described above (see Section 10.6.2.4 about control of reactant traffic). The deployment of zeolite barriers has been advocated as a means of increasing the selectivity of optical [291] and semiconductor–gas sensors [321–323]. These latter works, however, used catalyst bed-type filters (up to 250 mg), with a relatively large mass which leads to a slow sensor response. A more sophisticated approach was used by Fukui and Nishida [324], who used commercial crystals of FAU and FER zeolites with colloidal silica as a binder to cover the sensing layer of La<sub>2</sub>O<sub>3</sub>–Au/SnO<sub>2</sub> sensors, and obtained ethanol filtering effects that increased the CO selectivity. Different zeolite masks, also made of commercial crystals, were used to minimize the interference of O<sub>2</sub> in yttria-stabilized zirconia sensors used to analyze nitric oxide [325]. It has also been reported that the modification of semiconductor sensors by mechanically mixing MCM-41 with powdered SnO<sub>2</sub> gave rise to enhanced sensitivity to H<sub>2</sub> [326].

As it was mentioned above (see Section 10.6.2.4), Vilaseca et al. [215] have synthesized MFI and LTA films directly on a Pd-doped SnO<sub>2</sub> layer (see Figure 10.31). These molecular filters hindered the passage of undesired molecules and increased the concentration of the targeted species in the vicinity of the sensitive layer depending on their interactions with the zeolite pores and on the operating conditions. The results showed that a suitable zeolite film can strongly reduce, and in some cases suppress, the response of the sensor to certain species, and thereby increase the sensing selectivity (see Figure 10.32).

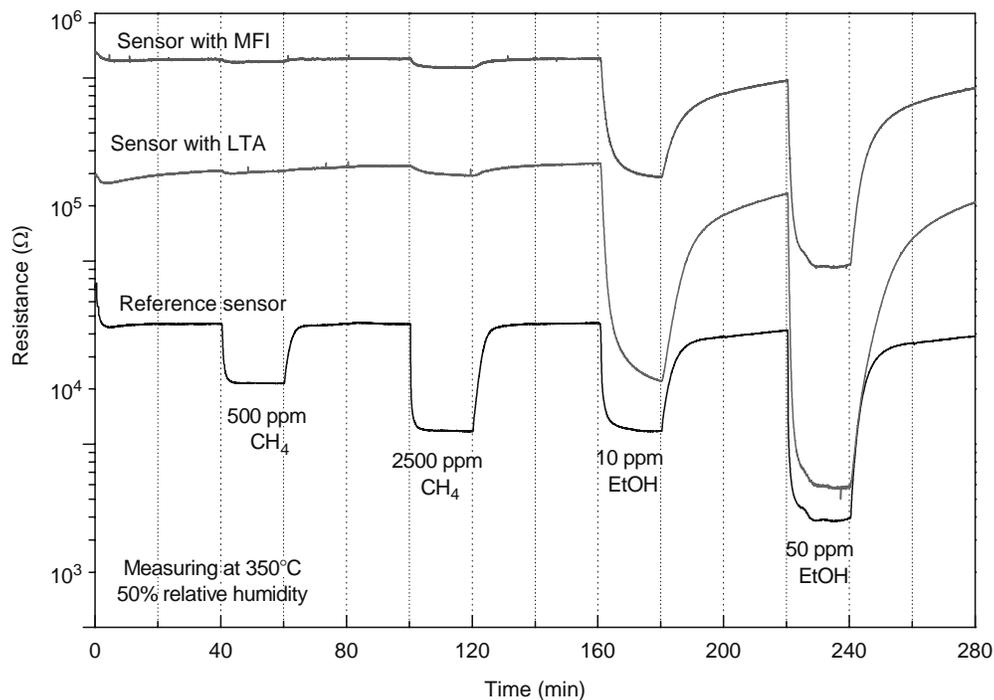

**FIGURE 10.31** (a) Top view of a Pd-SnO<sub>2</sub> layer, (b) cross section of a SIL-1 film on a Pd-SnO<sub>2</sub> layer, and (c) top view of a SIL-1 film onto a Pd-SnO<sub>2</sub> layer.

## 10.7 CONCLUSIONS

The efforts and advances during the last 15 years in zeolite membrane and coating research have made it possible to synthesize many zeolitic and related-type materials on a wide variety of supports of different composition, geometry, and structure and also to predict their transport properties. Additionally, the widely exploited adsorption and catalytic properties of zeolites have undoubtedly opened up their scope of application beyond traditional separation and pervaporation processes. As a matter-of-fact, zeolite membranes have already been used in the field of membrane reactors (chemical specialties and commodities) and microchemical systems (microreactors, microseparators, and microsensors).

Nevertheless, the availability of procedures allows the preparation of zeolite membranes and layers with sufficient quality, reproducibility, and reliability only up to a few hundred square centimeters in surface, delaying the industrial implementation of zeolite membrane-based technology. To be realistic, the lack of module reliability under extreme temperature cycling or harsh environment and the necessary raw material cost reductions (supports and chemicals) are two of the main challenges toward which strong efforts must be targeted.

**FIGURE 10.32** Response of Pd/SnO<sub>2</sub> sensors as measured resistance under different concentrations of CH<sub>4</sub> and EtOH.

## ACKNOWLEDGMENTS

We acknowledge the contribution to this chapter of all the current and former members of the Catalysis, Molecular Separations and Reactor Engineering Group at the University of Zaragoza. Particular thanks to Pilar Bernal, Daniel Picaeo, Miguel Urbiztondo, and Montse Vilaseca for their figures and SEM analysis. We would also like to thank the DGA (Aragon), MCYT (Spain), and UE for financial support. Finally, we are really grateful to Professor Santamaría and Dr. Coronas who encouraged us to write this chapter.

## 11.1 INTRODUCTION

There is a growing awareness by scientists, political leaders, and the general public, that the best way to approach the world's limited water resources problem lies in a coordinated approach involving water management, water purification, and water conservation [1–5]. Thermal and membrane systems are the two most successful commercial water purification techniques. Desalination using reverse osmosis (RO) membranes, in particular, has become very popular for producing freshwater from brackish water and seawater. The technique has low capital and operating costs compared to other alternative processes like multistage flash [6]. Ultrafiltration (UF) may be used before reverse osmosis for feed water pretreatment [7]. Membrane separation processes are also widely used in biochemical processing, in industrial wastewater treatment, in food and beverage production, and in pharmaceutical applications [8].

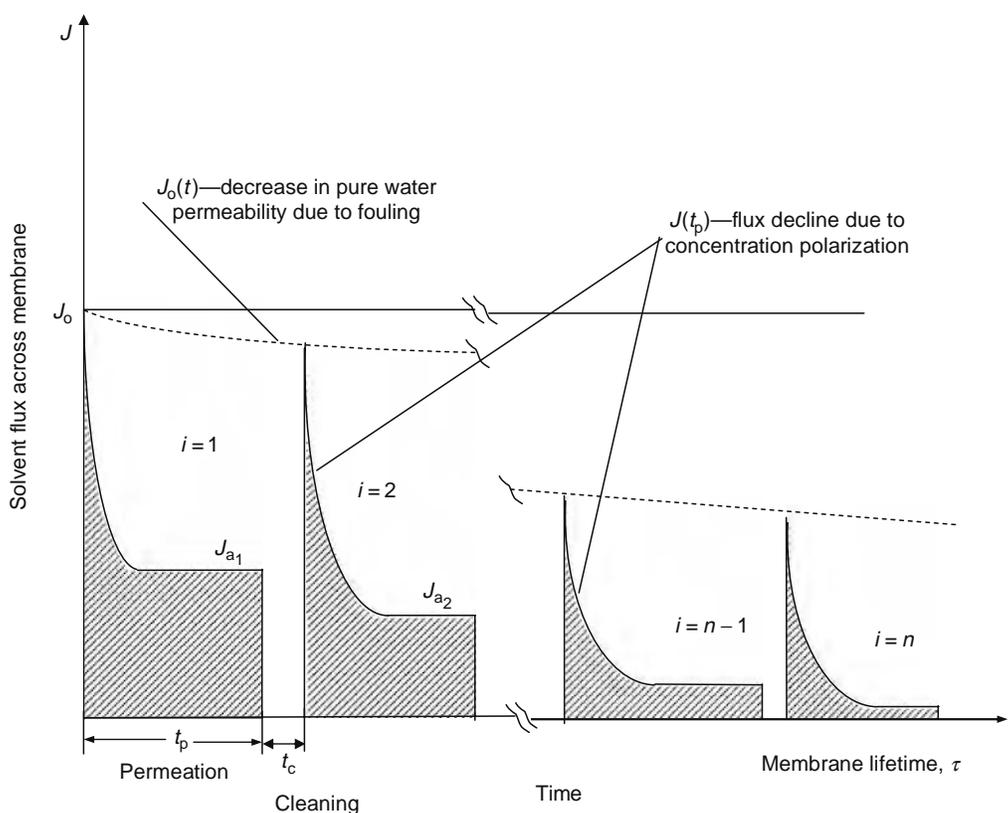

**FIGURE 11.1** A schematic representation of concentration polarization and fouling at the membrane surface. (From Goosen, M.F.A., Sablani, S.S., Al-Hinai, H., Al-Obeidani, S., Al-Belushi, R., and Jackson, D., *Sep. Sci. Technol.*, 39, 2261, 2004.)

Koltuniewicz and Noworyta [9], in a highly recommended paper, summarized the phenomena responsible for limiting the permeate flux during cyclic operation (i.e., permeation followed by cleaning). Membrane lifetime and permeate (i.e., pure water) fluxes are primarily affected by the phenomena of concentration polarization (i.e., solute build-up) and fouling/scaling (e.g., microbial adhesion, gel layer formation, and solute adhesion) at the membrane surface (Figure 11.1) [10]. During the initial period of operation within a cycle, concentration polarization is one of the primary reasons for flux decline,  $J_a$  (Figure 11.2). Large-scale membrane systems operate in a cyclic mode, where clean-in-place operation alternates with the normal run. Figure 11.2 shows a decrease in the flux for pure water from cycle to cycle,  $J_o(t)$ , due to fouling/scaling, the flux decline within a cycle due to concentration polarization,  $J(t_p)$ , and the average flux under steady-state concentration,  $J_a$ . The average flux under steady-state concentration decreasing from cycle-to-cycle suggests irreversible solute adsorption or fouling. Accumulation of the solute retained on a membrane surface leads to increasing permeate flow resistance at the membrane wall region.

One of the most serious forms of membrane fouling is bacterial adhesion and growth [11]. Once they form, biofilms can be very difficult to remove, either through disinfection or chemical cleaning. This wastes energy, degrades salt rejection, and leads to shortened membrane life. This is one area, for example, where further research is required.

A variety of liquids have been treated with reverse osmosis and ultrafiltration membranes ranging from seawater, to wastewater, to milk and yeast suspensions. Each liquid varies in composition and in the type and fraction of the solute(s) to be retained by the membrane. Complicating factors include the presence of substances such as oil in seawater and wastewater [12–15]. The presence of the oil normally necessitates an additional pretreatment step further complicating the fouling process. The presence of humic acids in surface water and wastewater also needs special attention [16,17]. The fouling phenomena, the preventive means (i.e., pretreatment), and the frequency and type of membrane cleaning cycle are all dependent on the type of liquid being treated.

Membrane materials for reverse osmosis and ultrafiltration applications range from polysulfone and polyethersulfone, to cellulose acetate and cellulose diacetate [12,18–23]. Commercially available polyamide composite membranes for desalination of seawater, for example, are available from a variety of companies in the United States, Europe, and Japan [24]. The specific choice of membrane material to use depends on the process (e.g., type of liquid to be treated and operating conditions) and economic factors (e.g., cost of replacement membranes and cost of cleaning chemicals). The exact chemical composition and physical morphology of the membranes may vary from manufacturer to manufacturer. Since the liquids to be treated and

**FIGURE 11.2** Diagram of typical flux–time dependency during cyclic operation in large-scale ultrafiltration systems. (From Koltuniewicz, A. and Noworyta, A., *Indus. Eng. Chem. Res.*, 33, 1771, 1994.)

the operating conditions also vary from application to application, it becomes difficult to conclude which materials are the best to use in order to inhibit membrane fouling.

Concentration polarization is an inherent part of a membrane separation process. Equipment design and operating conditions normally take care of it. Scaling/fouling, which is triggered by concentration polarization, reduces flux that can be minimized using antiscalants. Concentration polarization is not the same as fouling except that by theory it results in flux decline due to higher osmotic pressure and not due to resistance to flow particularly in RO. However, in UF where we deal with high molecular weight solutes, accumulation of large molecules in the boundary layer may cause resistance to flow. In UF, concentration polarization is more often treated as part of fouling but not in RO or nanofiltration (NF).

The primary aim of the chapter is to critically review the literature on the fouling phenomena in reverse osmosis and ultrafiltration membrane systems and methodologies for its minimization (i.e., the analytical techniques employed to quantify fouling, preventive means, and membrane cleaning methods). Fouling of membranes used in gas separation was also briefly reviewed. Specific recommendations were also made on how scientists, engineers, and technical staff can assist in improving the performance of membrane systems through fundamental and applied research.

## 11.2 MEMBRANE FOULING PHENOMENA

The main mechanisms of membrane fouling are adsorption of feed components, clogging of pores, chemical interaction between solutes and membrane material, gel formation and bacterial growth. Let us first consider bacterial growth on membranes. Microbiological fouling of reverse osmosis membranes is one of the main factors in flux decline and loss of salt rejection [25–29] (Table 11.1).

### 11.2.1 MICROBIOLOGICAL FOULING

Bacterial fouling of a surface (i.e., formation of a biofilm) can be divided into three phases: transport of the organisms to the surface, attachment to the substratum, and growth at the surface. Fleming et al. [30] show that bacterial fouling of a surface takes about 3 days to completely cover a reverse osmosis membrane with a biofilm. Ghayeni et al. [25,26] studied initial adhesion of sewage bacteria belonging to the genus *Pseudomonas* to reverse osmosis membranes. It was found that bacteria

would sometimes aggregate upon adhering. While minimal bacterial attachment occurred in a very low ionic strength solution, significantly higher numbers of attached microbes occurred when using salt concentrations corresponding to wastewater. Understanding the mechanism of bacterial attachment may assist in the development of antifouling technologies for membrane systems.

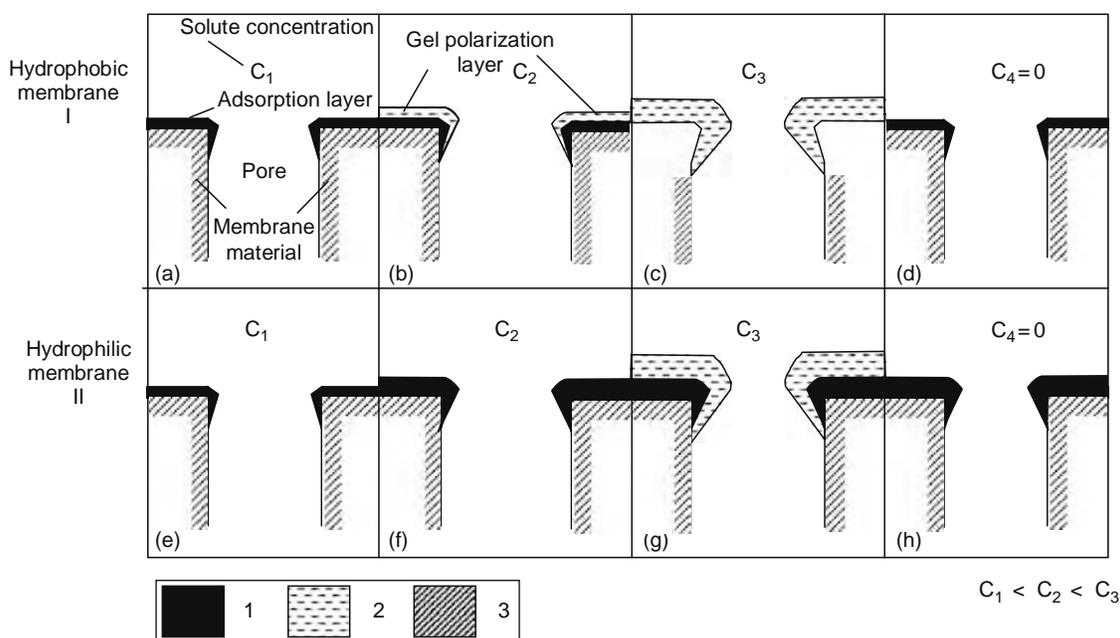

Flemming and Schaule [20] also demonstrated that after a few minutes of contact between a membrane and raw water, the first irreversible attachment of cells occurs. Their results suggest that membrane manufacturers should stay away from polyamide and polysulfone materials, at least for wastewater treatment applications. *Pseudomonas* was identified as a fast adhering species out of a tap water microflora. If non-starving cells were used (i.e., sufficient nutrients and dissolved oxygen in the raw water), the adhesion process improved with an increase in the number of cells in suspension. When starving cells were used, incomplete coverage of the surface occurred. This is similar to the surface aggregate formations observed for membranes by Ghayeni et al. [25,26]. Flemming and Schaule [20] also detected a biological affinity of different membrane materials toward bacteria. Polyetherurea, for example, had a significantly lower biological affinity than polyamide, polysulfone, and polyethersulfone.

In a similar but more thorough study than that performed by Ghayeni et al. [25], Ridgway et al. [28,31] in two excellent papers reported on the biofouling of reverse osmosis membranes with wastewater. Cellulose diacetate membranes became uniformly coated with a fouling layer that was primarily organic in composition. Calcium, phosphorous, sulfur, and chlorine were the major inorganic constituents detected. Protein and carbohydrate represented as much as 30% and 17%, respectively, of the dry weight of the biofilm. Electron microscopy revealed that the biofilm on the feed water side surface of the membrane was 10–20  $\mu\text{m}$  thick and was composed of several layers of compacted bacterial cells, many of which were partially or completely autolyzed. The bacteria were firmly attached to the membrane surface by an extensive network of extracellular polymeric fibrils. They showed that mycobacteria adhered to the cellulose acetate membrane surface 25-fold more effectively than a wild-type strain of *Escherichia coli*. In a key finding, the ability of *Mycobacterium* and *E. coli* to adhere to the membrane was correlated with their relative surface hydrophobicities as determined by their affinities for *n*-hexadecane [31]. The results suggested that hydrophobic interaction between bacterial cell surface components and the cellulose membrane surface plays an important role in the initial stages of bacterial adhesion and biofilm formation. A key question that arises is whether the importance of this hydrophobic interaction between the cell and the membrane also holds true for other polymers. This work is similar to that reported by Cherkasov et al. [32] on fouling resistance of hydrophilic and hydrophobic membranes (Figure 11.3). A later research study by Ridgway [33] confirmed these results and conclusions.

### 11.2.2 EFFECT OF HUMIC ACIDS ON FOULING LAYER

The degradation of organic matter, such as plants, in the soil produces a mixture of complex macromolecules called humic acids. These complex molecules have polymeric phenolic structures with the ability to chelate metals especially iron. It is recommended that humic acids be removed from process water before filtration by complexation (i.e., flocculation/coagulation; see Section 11.4.1). Humic acids give surface water a yellowish to brownish color and often cause fouling problems in membrane filtration [16,34]. The fouling tendency of humic acids appears to be due to their ability to bind to multivalent salts. Nystrom et al. [16], for example, showed that humic acids were most harmful in membranes that were positively charged (i.e., containing alumina and silica). Humic acids formed chelates with the metals (i.e., multivalent ions) and could be seen as a gel-like layer on the filter surface.

Schafer et al. [35] studied the role of concentration polarization and solution chemistry on the morphology of the humic acid fouling layer. Irreversible fouling occurred with all membranes at high calcium concentrations. Interestingly, it was found that the hydrophobic fraction of the humic acids was deposited preferentially on the membrane surface. This result is similar to the work of Ridgway et al. [31], who showed that the hydrophobic interaction between a bacterial cell surface and a membrane surface plays a key role in biofilm formation. The formation of two layers, one on top of the other, was also observed by Khatib et al. [36]. The formation of a Fe–Si gel layer directly on the membrane surface was mainly responsible for the fouling.

**FIGURE 11.3** Gel-layer formation on surface of an ultrafiltration membrane made from (I) hydrophobic and (II) hydrophilic material.  $C$ , solute concentration;  $C_1 < C_2 < C_3$ , 1 adsorption layer, 2 gel-polarization layer, 3 membrane material. (From Cherkasov, A.N., Tsareva, S.V., and Polotsky, A.E., *J. Membr. Sci.*, 104, 157, 1995.)

Reducing the electrostatic repulsion between the ferric gel and the membrane surface encouraged adhesion. Tu et al. [37] also showed that membranes with a higher negative surface charge and greater hydrophilicity were less prone to fouling due to fewer interactions between the chemical groups in the organic solute and the polar groups on the membrane surface.

What these studies tell us is that in order to reduce fouling due to humic acids, it is best to employ hydrophilic membranes, to have feed water with a low mineral salts content (e.g., calcium), and to work at low pH.

### 11.2.3 EFFECT OF INORGANICS, PROTEINS, AND COLLOIDS

Sahachaiyunta et al. [38] conducted dynamic tests to investigate the effect of silica fouling of reverse osmosis membranes in the presence of minute amounts of various inorganic cations such as iron, manganese, nickel, and barium, which are present in industrial and mineral processing wastewaters. Experimental results showed that the presence of iron greatly affected the scale structure on the membrane surface when compared to the other metal species.

A dual mode fouling process, similar to that observed for humic acids [35], was found for protein (i.e., bovine serum albumin [BSA]) fouling of microfiltration (MF) membranes. Protein aggregates first formed on the membrane surface followed by native (i.e., non-aggregated) protein. The native protein attached to an existing protein via the formation of intermolecular disulfide linkages.

Stable colloidal suspensions can cause less fouling. Yiantsios and Karabelas [39], in a very interesting paper, found that apart from particle size and concentration, colloid stability plays a major role in RO and UF membrane fouling. They demonstrated that standard fouling tests as well as most well-known fouling models are inadequate. A key finding was that the use of acid, which is a common practice to avoid scaling in desalination, might promote colloidal fouling. Lowering the pH reduces the negative charge on particles, causing aggregate formation that deposit on the membrane surface. Wastewater effluent organic matter was isolated into different fractions by Jarusutthirak et al. [40]. Each isolate exhibited different characteristics in fouling of NF and UF membranes. In particular, polysaccharides and amino sugars were found to play an important role in fouling. The colloidal fractions gave a high flux decline due to pore blockage, and hydrophobic interactions were very important for hydrophobic membranes causing a reduction in permeate flux.

### 11.2.4 TRANSITION FROM REVERSIBLE ADSORPTION TO IRREVERSIBLE FOULING

In a key study, Nikolova and Islam [29] reported that the decisive factor in flux decline was the adsorption resistance. With the development of a concentration polarization layer, the adsorbed layer resistance at the membrane wall increased linearly as a function of the solute concentration at the wall. They described the flux by the following relationship:

$$J = \frac{\Delta P - \Delta\pi(w)}{\mu(R_m + kC_w)} \quad (11.1)$$

where

$\Delta P$  is the hydraulic pressure difference across membrane

$C_w$  is the concentration at the membrane surface

$\Delta\pi(w)$  is the corresponding osmotic pressure

$R_m$  is the membrane resistance

$kC_w$  is the adsorbed layer resistance

$\mu$  is the fluid viscosity

In a key finding, they showed that the adsorption resistance was of the same order of magnitude as that of the membrane resistance. Surprisingly, the osmotic pressure was negligible in comparison to the applied transmembrane pressure. The significance of this study is that it showed that the reversible adsorbed solute layer at the membrane surface is the primary cause of flux decline and not the higher osmotic pressure at the membrane surface. This is supported by the work of Koltuniewicz and Noworyta [9] (Figure 11.2).

The transition between the reversible adsorption, described by Nikolova and Islam [29], and irreversible fouling is crucial to determining the strategy for improved membrane performance and for understanding the threshold values for which optimal flux and rejection can be maintained. In a very thorough study, Chen et al. [41] reported on the dynamic transition from concentration polarization to cake (i.e., gel layer) formation for membrane filtration of colloidal silica. Once a critical flux,  $J_{crit}$ , was exceeded, the colloids in the polarized layer formed a consolidated cake structure that was slow to depolarize and which reduced the flux. This paper is a very valuable source of information for membrane plant operators. By operating just below  $J_{crit}$  they can maximize the flux while at the same time reducing the frequency of membrane cleaning. A study by Chen et al. [41] showed that by controlling the flux below  $J_{crit}$ , the polarization layer may form and solute adsorption may occur but it is reversible and responds quickly to any changes in convection.

### 11.3 ANALYTICAL STRATEGIES

#### 11.3.1 MEASURING FOULING LAYER MORPHOLOGY AND CELL ADHESION KINETICS

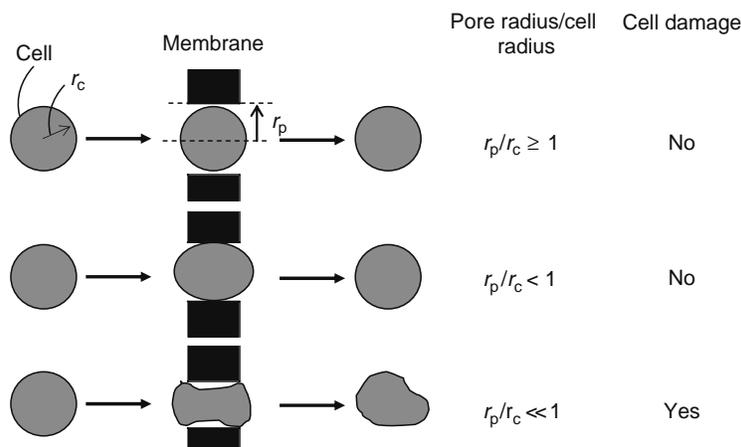

The smoothness of the membrane surface can influence the morphology of the fouling layer. Riedl et al. [42] employed an atomic force microscopy (AFM) technique to measure membrane surface roughness, and scanning electron microscopy (SEM) to assess the fouling layer. It was shown that smooth membranes produced dense surface fouling layer, whereas this same layer or biofilm on rough membranes was much more open. The primary conclusion of the study was that the fluxes through rough membranes are less affected by fouling formation than fluxes through smooth membranes.

The kinetics of adhesion of *Mycobacterium* sp. to cellulose diacetate reverse osmosis membranes have been described [19]. Adhesion of the cells to the membrane surface occurred within 1–2 h and exhibited saturation-type kinetics, which conformed closely to the Langmuir adsorption isotherm, a mathematical expression describing the partitioning of substances between a solution and a solid–liquid interface. This suggested that cellulose diacetate membrane surfaces may possess a finite number of available binding sites to which the mycobacteria can adhere. Treatment of the attached mycobacteria with different enzymes suggested that cell surface polypeptides, 4- or  $\alpha$ -1.6-linked glucan polymers, and carboxyl ester bond containing substances (possibly peptidylglycolipids) may be involved in the adhesion process. The exact molecular mechanisms of adhesion, however, have not as yet been clearly defined. This is one area where further research is needed.

#### 11.3.2 HYDRODYNAMIC STUDIES OF MICROBIAL ADHESION AND PASSAGE OF BACTERIA THROUGH MEMBRANES

Altena and Belfort [43] and Drew et al. [44] performed fundamental studies of the membrane fouling process based on the movement of rigid neutrally buoyant spherical particles (i.e., a model bacterial foulant) toward a membrane surface. While these researchers did not work directly with microbial cells, their hydrodynamic studies do provide useful information on how the particle size and fluid flow affect microbial adhesion. Their studies were an attempt to give clearer insight into the hydrodynamics behind the mechanism of microbial adhesion in RO systems. Under typical laminar flow conditions, particles with a radius smaller than 1  $\mu\text{m}$  were captured by a porous membrane surface (i.e., the microbial adhesion step) resulting in cake formation. Due to convective flow into the membrane wall, particles moved laterally toward the membrane. The particle concentration near the membrane surface increased significantly over that in the bulk solution and resulted in a fouling layer. In their cross-flow membrane filtration experiments there appeared to be two major causes for lateral migration: a drag force exerted by the fluid on the particle due to the convective flow into the membrane wall (i.e., wall suction effect or permeation drag force) that carried particles toward the membrane, and an inertial lift force that carried particles near the membrane away from the porous wall. For small particles ( $<1 \mu\text{m}$ ) the permeation drag force dominated. An expression was developed from the first principles to predict conditions under which a membrane module exposed to dilute suspensions of spherical particles will not foul.

In a recommended paper, Ghayeni et al. [45] studied the passage of bacteria (0.5  $\mu\text{m}$  diameter) through microfiltration membranes in wastewater applications. Membranes with pore sizes smaller than 0.2  $\mu\text{m}$  still transmitted secondary effluent cells. This is an interesting study, which showed that based on total cell counts (DAPI) up to 1% of the bacteria in the feed can pass to the permeate side. While a significant portion of the cells (e.g., 50%) in the permeate showed biological (CTC) activity, none of the cells were able to reproduce (i.e., culture on agar or in suspension). This is a good quantitative method for measuring cell injury. We can speculate that smaller cells, or membranes with larger pores, would allow for the passage of viable bacteria, which would be able to reproduce. This could occur at some critical cell/pore ratio (Figure 11.4).

**FIGURE 11.4** Passage of bacterial cells through membrane pores. Cell damage occurs at critical pore radius/cell radius ratio. (From Goosen, M.F.A., Sablani, S.S., Al-Hinai, H., Al-Obeidani, S., Al-Belushi, R., and Jackson, D., *Sep. Sci. Technol.*, 39, 2261, 2004.)

### 11.3.3 ANALYSIS OF DEPOSITS ON MEMBRANE SURFACE

Attenuated total reflection (ATR) Fourier transform infrared (FTIR) spectroscopy can provide insight into the chemical nature of deposits on membranes [46]. The spectra of the foulants can be easily distinguished from the spectra of the membrane material. ATR/FTIR can also indicate the presence of inorganic foulants as well as the ratio of inorganic–organic foulants.

The surface deposits on UF polyethersulfone (PES) membranes fouled by skimmed milk have been studied using ATR-FTIR to detect the functional groups of the fouling species [22]. Some milk components (Lactose and salts) were eliminated by water rinsing, while proteins were only partially removed by chemical cleaning at basic pH. For dynamic conditions, the cleanliness of the membrane was evaluated through two criteria: hydraulic (i.e., recovery of initial flux) and chemical (i.e., no more contaminants detected). The hydraulic cleanliness of the membrane was achieved, while the membrane initial surface state was not restored. ATR-FTIR is also a useful tool for evaluating other fouling species such as oil and humic acids.

Deposits on a membrane surface, before and after cleaning, can also be analyzed using SEM in combination with energy dispersive x-ray (EDX) combined with a microanalysis system permitting quantitative determination of elements [12]. Furthermore, identification of specific species deposited onto membrane surfaces can be carried out using matrix-assisted laser desorption ionization mass spectroscopy (MALDI-MS). Chan et al. [47] employed this technique to differentiate between desorption of proteins from the membrane surface, from the inside pores and from the membrane substrate. It has the potential for quantitative measurement of protein fouling on membrane surfaces. It was shown that the technique is a powerful tool for distinguishing between different proteins in fouling deposits.

Atomic force microscopy has proved to be a rapid method for assessing membrane–solute interactions (fouling) of membranes under process conditions [48]. Given the good agreement between the correlations using AFM and operating performance, it should be possible, in the future, to use these techniques to allow earlier assessment of the fouling propensity of process streams.

Nondestructive, real-time observation techniques to detect and monitor fouling during liquid separation processes are of great importance in the development of strategies to improve operating conditions. In a recommended paper by Li et al. [23], ultrasonic time-domain reflectometry (UTDR) was used to measure organic fouling, in real time, during ultrafiltration with polysulphone (PS) membranes. The feed solution was a paper-mill effluent, which contained breakdown products of lignin or lignosulphonate, from a wastewater treatment plant. Experimental results showed that the ultrasonic signal response can be used to monitor fouling-layer formation and growth on the membrane in real time. The differential signal developed indicated the state and progress of the fouling layer and gave warning of advanced fouling during operation.

### 11.3.4 MEASUREMENT OF CONCENTRATION POLARIZATION

Gowman and Ethier [49,50] developed an automated laser-based refractometric technique to measure the solute concentration gradient during dead-end filtration of a biopolymer solution. This paper attempts to reconcile theory with experimental data. The refractometric technique may be useful to other researchers working on quantification of membrane fouling.

A nuclear magnetic resonance technique was employed by Pope et al. [13] to quantitatively measure the concentration polarization layer thickness during cross-flow filtration of an oil–water emulsion. This method helps to clarify the relative quantitative contributions to flux decline of the adsorbed layer resistance, and the concentration polarization layer gradient and thickness. It helps to explain the flux declines due to different resistances as shown in Figure 11.2. The technique, which measured layer thickness using chemical shift selective microimaging, may be useful in studying other membrane fouling situations that occur in food processing and desalination.

### 11.3.5 MATHEMATICAL MODELS FOR FLUX DECLINE

A series resistance model was developed by Dal-Cin et al. [51] to quantify the relative contributions of adsorption, pore plugging, and concentration polarization to flux decline during UF of a pulp mill effluent. They proposed a relative flux loss ratio as an alternative measure to the conventional resistance model that was found to be a misleading indicator of the flux loss. Using experimental and simulated flux data, the series resistance model was shown to under-predict fouling due to adsorption and to overpredict concentration polarization. This appears to be a disadvantage and would make the model of limited use in its current form. As mentioned in the introduction, Koltuniewicz and Noworyta [9] modeled the flux decline as a result of the development of a concentration polarization layer based on the surface renewal theory developed by Danckwerts [52]. The surface renewal model is more realistic than the commonly used film model since mass transfer at the membrane boundary layer is random in nature due to membrane roughness. Specifically, the membrane is not covered by a uniform concentration polarization layer, as was assumed in the film model, but rather by a mosaic of small surface elements with different ages, and, therefore, different permeate flow resistance. Any element can be swept away randomly by a hydrodynamic impulse, and then a new element starts building up a layer of retained solute at the same place on the membrane surface. They showed that the decrease in flux with respect to time,  $J(t_p)$ , due to the development of the concentration polarization layer is given by the following equation that also takes into account the rate of membrane surface renewal,  $s$  (area/unit time):

$$\bar{J}(t_p) = (J_o - J^*) \frac{s}{s + A} \frac{1 - e^{-(s+A)t_p}}{1 - e^{-st_p}} + J^* \quad (11.2)$$

where

- $A$  is the rate of loss of membrane surface area as a function of time
- $J_o$  is the initial value of the flux
- $J^*$  is the flux observed after infinite time
- $t_p$  is the time of permeation

$$s = A \frac{J_{\text{lim}} - J^*}{J_o - J_{\text{lim}}} \quad (11.3)$$

where  $J_{\text{lim}}$  is the limiting flux that is similar to critical flux,  $J_{\text{crit}}$ . The former can be obtained from literature data. The average flux under steady-state conditions,  $J_a$ , can be calculated directly from Equation 11.6 as a limit:

$$\bar{J}_a = \lim_{t_p \rightarrow \infty} \bar{J}(t_p) = (J_o - J^*) \frac{s}{A + s} + J^* \quad (11.4)$$

In support of this model, calculated values of flux using Equations 11.2 and 11.3 agreed well with experimental data. Equations 11.2 and 11.3 describe a permeation cycle of duration,  $t_p$ , as shown in Figure 11.2. This is a highly recommended paper for those who are operating large-scale continuous ultrafiltration plants, and to a certain extent RO plants. The model developed describes not only the dynamic behavior of a plant, but also allows for optimization of operating conditions (i.e., permeation time, cleaning time, and cleaning strategy).

### 11.3.6 VARIATION IN GEL-LAYER THICKNESS ALONG FLOW CHANNEL

In the case of cross-flow filtration, one can expect that the gel-layer thickness and the surface concentration of the solute will vary with distance from the channel entrance. As a consequence, the local permeate flux will also vary with longitudinal position. In a highly recommended article, Denisov [53] presented a mathematically rigorous theory of concentration polarization in cross-flow ultrafiltration, which takes into account the nonuniformity of the local permeate membrane flux. He derived equations describing the pressure/flux curve.

In the case of the gel-layer model, the theory led to a simple analytical formula for a limiting or critical flux,  $J_{\text{lim}}$ . The flux turned out to be proportional to the cube root of the ratio of the gel concentration to the feed solution concentration, rather than to the logarithm of this ratio, as the simplified Michaels–Blatt theory predicted:

$$J_{\text{lim}} = \left(\frac{3}{2}\right)^{(2/3)} KP_g = 1.31 \left(\frac{C_g}{C_o}\right) \frac{m^{1/3} D^{2/3} U_o^{1/3}}{L^{1/3} h^{1/3}} \quad (11.5)$$

where

$$P_g = \left(\frac{C_g m D^2 U_o}{C_o K^3 L h}\right) \quad (11.6)$$

where

- $K$  is the hydraulic permeability of membrane to pure solvent ( $\text{m}^3/\text{Ns}$ )
- $C_g$  is the gel concentration ( $\text{kmol}/\text{m}^3$ )
- $C_o$  is the solute concentration in feed solution ( $\text{kmol}/\text{m}^3$ )
- $m$  is the channel parameter
- $D$  is the solute diffusion coefficient ( $\text{m}^2/\text{s}$ )
- $U_o$  is the longitudinal component of fluid velocity averaged over the channel cross-section ( $\text{m}/\text{s}$ )
- $L$  is the channel length ( $\text{m}$ )
- $h$  is the transversal dimension of the channel ( $\text{m}$ )

In the case of the osmotic-pressure model, the rigorous theory allowed the conclusion that at high applied transmembrane pressure, the permeate flux increased as a cube root of the pressure, so that the limiting flux was never reached:

$$\bar{J} \approx \left(\frac{3}{2}\right)^{2/3} K \bar{P}^{1/3} P_o^{2/3} \approx 1.31 \left(\frac{\bar{P}}{RTC_o}\right)^{1/3} \frac{m^{1/3} D^{2/3} U_o^{1/3}}{L^{1/3} h^{1/3}} \quad (11.7)$$

where

$$P_o = \left(\frac{mD^2U_o}{RTC_oK^3Lh}\right) \quad (11.8)$$

where

$J$  is the average flux over the channel (m/s)

$P$  is the transmembrane pressure (N/m<sup>2</sup>)

$R$  is the gas constant (J/kmol K)

$T$  is the temperature (K)

However, one minor weakness of the study was that the analysis ignored the concentration dependence of the viscosity and the partial transmission of the solute through the membrane.

### 11.3.7 PORE BLOCKAGE AND CAKE FORMATION

Cake formation, shear forces, and other mathematical aspects and the kinetics of the boundary layer are described in a study by Hermia [54]. To understand the effect of membrane fouling on system capacity the  $V_{\max}$  test is often used to accelerate testing. This test assumes that fouling occurs by uniform constriction of the cylindrical membrane pores. This does not happen in practice. Zydney and Ho [27] examined the validity of the  $V_{\max}$  model and compared the results with predictions from a new model that accounts for fouling due to both pore blockage and cake formation. It was found that the  $V_{\max}$  analysis significantly overestimates the system capacity for proteins that foul primarily by pore blockage, but it underestimates the capacity for compounds that foul primarily by cake formation. In contrast the pore blockage–cake filtration model provides a much better description of membrane fouling, leading to more accurate sizing and scale-up of normal flow filtration devices.

## 11.4 METHODOLOGIES FOR MINIMIZATION OF MEMBRANE FOULING

### 11.4.1 FEED WATER PRETREATMENT USING FILTRATION AND FLOCCULATION

Reverse osmosis seawater systems that operate on surface feed water normally require an extensive pretreatment process to control membrane fouling. Recently new effective water microfiltration technologies have been introduced commercially. Wilf and Klinko [55] and Glueckstern et al. [56] noted that these developments can improve the quality of surface seawater feed to a level comparable to or better than the water quality from well water sources. The utilization of capillary ultrafiltration as a pretreatment step enabled operation of the reverse osmosis system at a high recovery (15%) and permeate flux rate. In a similar study utilizing micro- and ultrafiltration as seawater pretreatment steps for reverse osmosis, Glueckstern and Priel [57] showed that such technology can dramatically improve the quality of the feed water. This is especially important if cooling water from existing power stations is used as feed water for desalination plants.

The reuse of municipal wastewater requires treatment to an acceptable quality level that satisfies regulatory guidelines. Ghayani et al. [25] employed hollow fiber microfiltration as a pretreatment for wastewater for RO in the production of high-quality water. Organisms present in MF-treated secondary effluent were able to attach to RO membranes and proliferate to form a biofilm. Total cell counts in this treated effluent (i.e., permeate from the MF unit) were several orders of magnitude higher than viable cell counts. This was confirmed in a later study [45]. What these results indicate is that microfiltration membranes will not be totally effective in the removal of bacteria from the feed water stream. The result showed that most cells were severely damaged by passage through the membrane (Figure 11.4). However, we can speculate that this damaging effect may be strain-specific and dependent on the cell/pore diameter.

In a study by Chapman et al. [58], a flocculator was used to remove suspended solids (SDI), organics, and phosphorus from wastewater. The flocculator produced uniform microflocs, which were removed by cross-flow microfiltration. Flocculated particles can form a highly porous filtration cake on a membrane surface. This will help inhibit fouling on the membrane by preventing the deposition of particles and therefore reducing the number of membrane cleaning cycles [59]. In practice SDI and modified fouling index are used to reflect the fouling potential.

Arsenic removal from drinking water is a major problem in many parts of the world. Han et al. [60] investigated arsenic removal by flocculation and microfiltration. Ferric chloride and ferric sulfate were used as flocculants. Results showed that flocculation before microfiltration led to significant arsenic removal in the permeate. Furthermore, the addition of small amounts of cationic polymeric flocculants resulted in significantly improved permeate fluxes during microfiltration.

Another commonly used method is coagulation. This technique removes turbidity from water by the addition of cationic compounds. The usefulness of coagulation as a pretreatment to remove microparticles in aqueous suspension before a membrane filtration was shown by Choksuchart et al. [61]. There are several types of coagulation systems. Comparisons were made by Park et al. [62] between coagulation with only rapid mixing in a separate tank (i.e., ordinary coagulation), and coagulation with no mixing tank (i.e., in-line coagulation) before an ultrafiltration process. The ordinary coagulation was superior. An in-line coagulation (without settling) UF process was also employed by Guigui et al. [63]. Floc cake resistance was found to be lower than resistance due to the unsettled floc and the uncoagulated organics. A reduction in coagulant dose induced an increase in the mass transfer resistance.

Combining flocculation and coagulation in a pretreatment process has also been studied. In a key paper by Lopez-Ramirez et al. [64], the secondary effluent from an activated sludge unit was pretreated, before RO, with three levels: intense (coagulation–flocculation with ferric chloride and polyelectrolite and high pH sedimentation), moderate (coagulation–flocculation with ferric chloride and polyelectrolite and sedimentation), and minimum (only sedimentation). The optimum for membrane protection, in terms of calcium, conductivity, and bicarbonates reduction, was the intense treatment. Membrane performance varied with pretreatment but not reclaimed water quality. The study recommended intense pretreatment to protect the membrane.

A modular pilot size plant involving coagulation/flocculation, centrifugation, ultrafiltration, and sorption processes was designed and constructed by Benito et al. [13] for the treatment of oily wastewaters. Empirical equations developed by Shaalan [65] predict the impact of water contaminants on flux decline. These formulae enable decision-making concerning a suitable water pretreatment scheme and also selection of the most appropriate cleaning cycle.

#### 11.4.2 EFFECTS OF SPACERS ON PERMEATE FLUX AND FOULING

The influence of spacer thickness, in spiral-wound membrane units, on permeate flow and its salinity was studied by Sablani et al. [7]. Membrane parameters were also estimated using an analytical osmotic pressure model for high salinity applications. The effects of spacer thickness on permeate flux showed that the observed flux decreases by up to 50% going from a spacer thickness of 0.1168–0.0508 cm. The authors commented that the different geometry/configuration of the spacer-influenced turbulence at the membrane surface and that, in turn, affected concentration polarization. This suggested less turbulence with the smaller spacer thickness and is opposite to what is normally expected. A membrane module with an intermediate spacer thickness of 0.0711 cm was found to be the best economically, since it gave the highest water production rate (L/h).

Geraldes et al. [66] assessed the effect of a ladder-type spacer configuration in NF spiral-wound modules on concentration boundary layer disruption. The results showed that the average concentration polarization for the membrane wall was independent of the distance to the channel inlet, while for the membrane wall without adjacent filaments the average concentration polarization increased with the channel length. This was due to the fact that in the first case the transverse filaments periodically disrupted the concentration boundary layer while in the second case the concentration boundary layer grew continuously along the channel length. The experimental results of the apparent rejection coefficients were compared to model predictions, the agreement being good. Their results clearly established how crucial the spacers configuration is in the optimization of the spiral-wound module efficiency.

The unexpected results of Sablani et al. [7] (i.e., less turbulence with smaller spacer thickness) may be best explained by an excellent paper by Schwinge et al. [67]. The latter employed computational fluid dynamics (CFD) in a study of unsteady flow in narrow spacer-filled channels for spiral-wound membrane modules. The flow patterns were visualized for different filament configurations incorporating variations in mesh length, filament diameter, and for channel Reynolds numbers,  $Re_{ch}$ , up to 1000. The simulated flow patterns revealed the dependence of the formation of recirculation regions on the filament configuration, mesh length, filament diameter, and the Reynolds number. When the channel Reynolds number was increased above 300, the flow became super-critical showing time-dependent movements for a filament located in the center of a narrow channel; and when the channel Reynolds number was increased above 500 the flow became super-critical for a filament adjacent to the membrane wall. For multiple filament configurations, flow transition can occur at channel Reynolds numbers as low as 80 for the submerged spacer at a very small mesh length (mesh length/channel height ( $l_m/h_{ch}$ ) = 1) and at a slightly larger Reynolds number at a larger mesh length ( $l_m/h_{ch}$  = 4). The transition occurred above  $Re_{ch}$  of 300 for a cavity spacer and above  $Re_{ch}$  of 400 for a zigzag spacer. We can speculate that the conclusions of Sablani et al. [7], less turbulence with smaller spacer thickness, were due to fewer recirculating regions as a result of smaller mesh length and filament diameter.

Computational fluid dynamics simulations were used by Li et al. [68] to determine mass transfer coefficients and power consumption in channels filled with nonwoven net spacers. The geometric parameters of a nonwoven spacer were found to have a great influence on the performance of a spacer in terms of mass transfer enhancement and power consumption. The results from the CFD simulations indicated that an optimal spacer geometry exists.

### 11.4.3 MEMBRANE SURFACE MODIFICATION

Belfer [24] described a simple method for surface modification of commercial composite polyamide reverse osmosis membranes. The procedure involved radial grafting with a redox system consisting of potassium persulfate/sodium methabisulfite. ATR-FTIR provided valuable information about the degree of grafting and the microstructure of the grafted chain on the membrane surface. Both acrylic and sulfo-acidic monomers and neutral monomers, such as polyethylene glycol methacrylate, were used to demonstrate the wide possibilities of the method in terms of grafting of different monomers and initiators. It was shown that some of the modified membranes conserved their previous operating characteristics, flux, or rejection, but exhibited a higher resistance to humic acid. Additional work needs to be done to find out what happens to the fouling resistance of such membranes over the long term (i.e., after initial biofilm formation).

A fouling-resistant reverse osmosis membrane that reduces microbial adhesion was reported by Jenkins and Tanner [69]. In this interesting study that confirmed the results of Flemming and Schaule [20], they compared two types of thin-film composite membranes with different chemistries. One type was classified as a polyamide, the other utilized a new chemistry that formed a polyamide-urea barrier (i.e., surface) layer. The latter composite membrane proved superior in reverse osmosis operation similar to that of the polyetherurea membrane of Flemming and Schaule [20], including rejection of certain dissolved species and fouling-resistance. These results suggest that the presence of urea groups in the membrane reduces microbial adhesion, perhaps through charge repulsion. The results of work by Ridgway [19] on the kinetics of adhesion of *Mycobacterium* sp. to cellulose diacetate reverse-osmosis membranes have similar implications. Scientists should therefore be able to minimize microbial adhesion by controlling the surface chemistry of polymer membranes, through, for example, the inclusion of urea groups.

Chemical modification of a membrane surface can be used in combination with spacers and periodic applications of bioacids [70]. The paper by Redondo, however, is short on specifics (e.g., details of chemical modification of aromatic polyamides membrane surface), and therefore not very useful to those looking for insights into membrane fouling.

### 11.4.4 FOULING RESISTANCE OF HYDROPHILIC AND HYDROPHOBIC MEMBRANES

Cherkasov et al. [32] presented an analysis of membrane selectivity from the standpoint of concentration polarization and adsorption phenomena. The results of their study showed that hydrophobic membranes attracted a thicker irreversible adsorption layer than hydrophilic membranes. The layer thickness was determined by the intensity of concentration polarization (Figure 11.3). This may be due to the stronger attraction of water to hydrophilic membranes. Kabsch-Korbutowicz et al. [17] also demonstrated that the most hydrophilic of the membranes tested (i.e., regenerated cellulose) had the lowest proneness to fouling by organic colloids (i.e., humic acids). These conclusions were further supported by the thorough work of Tu et al. [37] who showed that membranes with a higher negative surface charge and greater hydrophilicity was less prone to fouling due to fewer interactions between the chemical groups in the organic solute and the polar groups on the membrane surface.

### 11.4.5 CONTROL OF OPERATING PARAMETERS AND CRITICAL FLUX

A comprehensive difference model was developed by Madireddi et al. [71] to predict membrane fouling in commercial spiral-wound membranes with various spacers. This is a useful paper for experimental studies on the effect of flow channel thickness on flux and fouling. Avlonitis et al. [72] presented an analytical solution for the performance of spiral-wound modules with seawater as the feed. In a key finding they showed that it was necessary to incorporate the concentration and pressure of the feed into the correlation for the mass transfer coefficient. In a similar study, Boudinar et al. [73] developed the following relationship for calculating mass transfer coefficients in channels equipped with a spacer:

$$k = 0.753 \left( \frac{K}{2-K} \right)^{1/2} \frac{D_S}{h_B} Sc^{-1/6} \left( \frac{Pe h_B}{M} \right) \quad (11.9)$$

where

$Pe$  = Peclet number

$K = 0.5$

$M = 0.6$  (cm)

Controlled centrifugal instabilities (called Dean vortices), resulting from flow around a curved channel, were used by Mallubhotla and Belfort [74] to reduce both concentration polarization and the tendency toward membrane fouling. These vortices enhanced back-migration through convective flow away from the membrane-solution interface and allowed for increased membrane permeation rates.

Goosen et al. [3] showed that the polymer membrane can be very sensitive to changes in the feed temperature. There was up to a 100% difference in the permeate flux between feed temperatures of 30°C and 40°C. A more recent study showed that the improved flux was due primarily, though not completely, to viscosity effects on the water. Reversible physical changes in the membrane may also have occurred [75].

The transition from concentration polarization to fouling is a key phase in membrane separation processes that occur at a critical flux. Song [76] indicated that in most theories developed, the limiting or critical flux is based on semiempirical knowledge rather than being predicted from fundamental principles. To overcome this shortcoming, he developed a mechanistic model, based on first principles, for predicting the limiting flux. Similar to the critical flux results of Chen et al. [41] and the limiting flux of Koltuniewicz and Noworyta [9], Song showed that there is a critical pressure for a given suspension. When the applied pressure is below the critical pressure, only a concentration polarization layer exists over the membrane surface. A fouling layer, however, will form between the polarization and the membrane surface when the applied pressure exceeds the critical pressure. The limiting or critical flux values predicted by the mechanistic model compared well with the integral model for a low concentration feed. Operators of RO/UF plants/units should therefore operate their systems just below the critical flux in order to maximize productivity while minimizing membrane fouling.

#### 11.4.6 MEMBRANE CLEANING USING CHEMICAL AGENTS AND BACK PULSING

Membranes used in the food industry for ultrafiltration of milk or whey are cleaned on a regular basis with water and various aqueous solutions to ensure hygienic operation and to maintain membrane performance. Water quality, therefore, is of special importance in the rinsing and cleaning process as impurities present in the water could affect cleaning efficiency, and in the long term, contribute to a reduction in performance and life of the membrane [77]. Membrane manufacturers generally recommend the use of high-quality water such as filtered and demineralized water. Installing and running water purification systems, however, is expensive. Alternatively, water treatment chemicals such as sequestering agents (e.g., EDTA, polyphosphates) can be added to low-quality water to increase the solubility of metal ions such as calcium, magnesium, manganese, and iron. Reverse osmosis permeate may also be of suitable quality for use in cleaning.

In a study by Tran-Ha and Wiley [77], it was shown that impurities such as particulate and dissolved salts present in the water can affect the cleaning efficiency of a polysulphone ultrafiltration membrane. The water used for cleaning was doped with a known amount of specific ions (i.e., calcium, sodium, chloride, nitrate, and sulphate). The presence of calcium in water, at the usual concentrations found in tap water, did not greatly affect cleaning efficiency while chloride was found to reduce it. Sodium, nitrate, and sulphate appeared to improve the flux recovery during membrane cleaning. The cleaning efficiency was also improved at higher ionic strengths. For further reading a similar study by Lindau and Jonsson [12] is recommended. They assessed the influence of different types of cleaning agents on a polysulphone ultrafiltration membrane after treatment of oily wastewater.

The effect of different cleaning agents on the recovery of the fouled membrane was studied by Mohammadi et al. [78]. Results showed that a combination of sodium dodecyl sulfate and sodium hydroxide can be used as a cleaning material to reach the optimum recovery of the polysulfone membranes used in milk concentration industries. Also a mixture of sodium hypochlorite and sodium hydroxide showed acceptable results, where washing with acidic solutions was not effective.

Mores and Davis [79], to view membrane surfaces at different times in cross-flow microfiltration, used direct visual observation (DVO) of yeast suspensions with rapid back pulsing at varied back pulsing duration and pressure. The DVO photos showed that the membranes were more effectively cleaned by longer back pulse durations and higher back-pulse pressures. However, trade-offs existed between longer and stronger back pulses, and permeate loss during the back pulse. Shorter, stronger back pulses resulted in higher net fluxes than longer, weaker back pulses.

Roth et al. [80] proposed a method to determine the state of membrane wear by analyzing sodium chloride stimulus-response experiments. The shape of the distribution of sodium chloride in the permeate flow of the membrane revealed the solute permeation mechanisms for used membranes. For new membranes the distribution of sodium chloride collected in the permeate side as well in the rejection side was unimodal. For fouled membranes they noted the presence of several modes. The existence of a salt leakage peak, as well as an earlier detection of salt for all the fouled membranes, gave evidence of membrane structure modification. The intensive use of the membranes might have created an enlargement of the pore sizes. Salt and solvent permeabilities increased as well. While this is a difficult paper to follow, it may be of use to those who want to develop new methods for measuring membrane degradation.

Ammerlaan et al. [21] reported on membrane degradation resulting in a premature loss of salt rejection by cellulose acetate membranes. Tests were initiated to find a solution to the problem and to gain a better understanding of the mechanisms involved. It was found that removal of all free chlorine solved the problem. This was accomplished by injecting ammonia in the feed water presumably resulting in the formation of ammonium chloride. Membrane damage by chlorine was also reported by Ridgway et al. [18]. They studied membrane fouling at a wastewater treatment plant under low- and high-chlorine conditions. High-chlorine residuals damaged the membrane structure and reduced mineral rejection capacity.

## 11.5 MEMBRANE FOULING AND GAS SEPARATIONS

Many industrial activities, such as gas production [81–83], catalysis [84], and fuel cells [83], require gas separation. Fouling in gas separation processes, however, is less severe than in microfiltration, nanofiltration, and reverse osmosis where it is the main cause of permanent flux decline and loss of product quality [81].

Saracco and Specchia [84] noted that inorganic membranes have great potential in gas separation, catalytic reactors, gasification of coal, water decomposition, and solid electrolyte fuel cells [81–89]. Inorganic membranes are usually made from alumina, silica, carbon, and zeolites [85]. We will only assess porous membranes since fouling is virtually absent in dense membranes [81].

Roque-Malherbe et al. [90] studied the transport of hydrogen and carbon dioxide through porous ceramic membranes (Figure 11.5). The transport mechanism followed the Darcy law [81,82,88,89,91]:

$$J = B \left( \frac{\Delta P}{l} \right) = \Pi \Delta P = \frac{QV_m}{A} \quad (11.10)$$

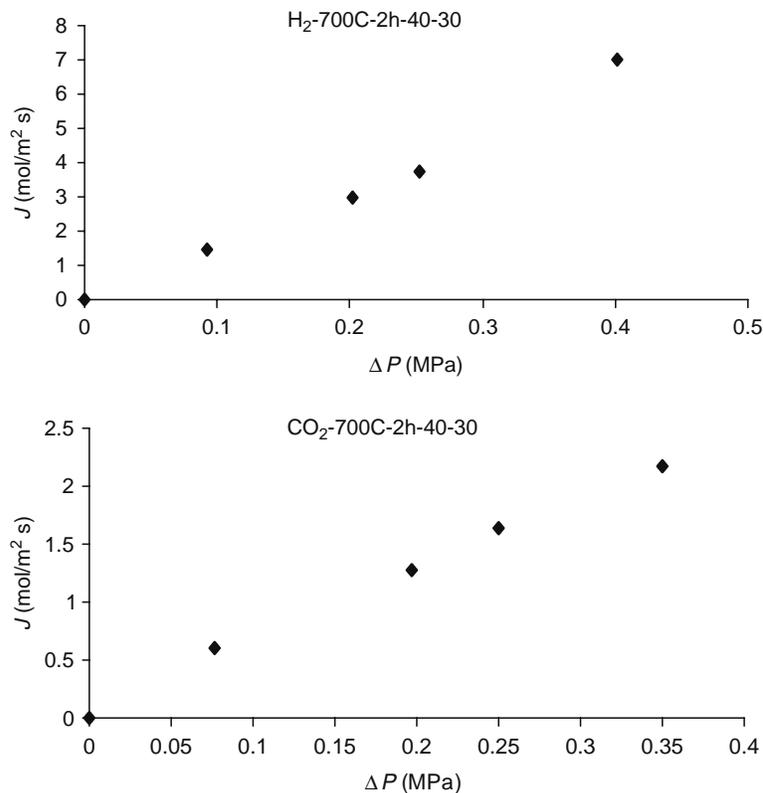

$$\Pi = \frac{B}{l} \quad (11.11)$$

Darcy law for gaseous laminar flow (Figure 11.5) is described by the following equation [88]:

$$Q = \left( \frac{k}{\mu} \right) * A * \left( \frac{\Delta P}{l} \right) \quad (11.12)$$

where

$$B = \frac{kV_m}{\mu} \quad (11.13)$$

**FIGURE 11.5** Study of the relation between the flux  $J$  and  $\Delta P$ , during the transport of H<sub>2</sub> and CO<sub>2</sub> through a porous ceramic membrane produced by thermal treatment of a natural zeolite. (From Roque-Malherbe, R., Applications of natural zeolites in pollution abatement and industry. In: Nalwa, H.S., ed., *Handbook of Surfaces and Interfaces of Materials*, Vol. 5, Academic Press, New York, 2001.)

The Carman–Kozeny equation for the permeability factor for a membrane formulated with pressed spherical particles is [88]:

$$k = \frac{\varepsilon d_v^2}{16C} \quad (11.14)$$

$$\varepsilon = 1 - \frac{\rho_A}{\rho_R} \quad (11.15)$$

therefore

$$k \approx \frac{\varepsilon d_v^2}{77} \quad (11.16)$$

As the membrane pore dimensions decrease, for example, due to pore blockage, or the mean free path of the molecules increase, the permeating particles tend to collide more with the pore walls than among themselves, then the Knudsen flow regime is established. In this case the expression for the permeation flux across the membrane is given by [83]:

$$J = \left( \frac{G}{(2MRT)^{1/2}} \right) * \left( \frac{\Delta P}{l} \right) \quad (11.17)$$

where  $G$  is the geometrical factor which accounts for membrane porosity and tortuosity.

Flux decline as a result of membrane fouling can be attributed to pore blocking due to the deposition of particles flowing with the gas to be cleaned. In addition, a decrease in the membrane porosity and consequently flux decay, during the gas separation process, could be produced in ceramic membranes because of the sinterization of the particles which constitutes the membrane, if the gas separation process is carried out at high temperatures. This means physical changes in the membrane can occur as a result of the operating parameters. Pore blockage and membrane compaction are two factors that contribute to fouling of membranes during gas separations.

## 11.6 ECONOMIC ASPECTS OF MEMBRANE SEPARATIONS

New separation techniques must, at minimum, be comparable in overall cost, and preferably be lower in cost than traditional technology. Scientists often forget that successful commercialization of a new technology is dependent on economic factors. Just because a novel separation technique works in the laboratory, for example, does not mean that it will replace current methods.

The competitiveness of UF pretreatment in comparison to conventional pretreatment (i.e., coagulation and media filtration) was assessed by Brehant et al. [92] by looking at the impact on RO hydraulic performances. The study showed that ultrafiltration provided permeate water with high and constant quality resulting in a higher reliability of the RO process than with a conventional pretreatment. The combination of UF with a pre-coagulation at low dose helped in controlling UF membrane fouling. The authors concluded that the combined effect of a higher recovery and a higher flux rate promised to significantly reduce the RO plant costs. The conclusions reached were opposite of those reported in the paper by Glueckstern et al. [56] above, and demonstrate the complexity of the overall economics of a membrane separation process.

Field evaluation of a hybrid membrane system consisting of an UF membrane pretreatment unit and an RO seawater unit was conducted by Glueckstern et al. [56]. For comparison a second pilot system consisting of conventional pretreatment and an RO unit was operated in parallel. The conventional pretreatment unit included in-line flocculation followed by media filtration. The study showed that UF provided a very reliable pretreatment for the RO system independent of the raw water quality fluctuations. However, the cost of membrane pretreatment was higher than conventional pretreatment. This suggested that membrane pretreatment for RO desalting systems is only economic for sites that require extensive conventional pretreatment or where wide fluctuations in the raw water quality are expected.

## 11.7 CONCLUDING REMARKS

Membrane fouling is a complex process where the physicochemical properties of the membrane, the type of cells, the quality of the feed water, the type of solute molecules, and the operating conditions all play a role. The end result of most membrane separations is a fouled surface that the operator will not be able to clean to its original state. To reduce the tendency to irreversible fouling it is essential to operate the plant/unit below the critical flux. This must go hand-in-hand with reliable feed water pretreatment schemes.

Studies are required on effective removal of biofilms without damaging the membrane. Additional work needs to be done to find out what happens to the fouling resistance of chemically modified membranes over the long term (i.e., after initial biofilm formation). Membrane resistance to humic acids is another area for further study. Furthermore, the molecular tools needed for exploring the biochemical details of the microbial adhesion process to membranes are now available.

Various aspects of the water problem need to be considered not only by developing nations but also by developed countries. Water is required for urban development, industrialization, and agriculture. An increase in the world population results in an increase in water usage. We can stipulate that in the future, serious conflicts will arise not because of a lack of oil, but due to water shortages. As scientists and engineers continue to improve the technical and economic efficiency of membrane desalination systems, it is imperative that we do not lose sight of the bigger water resources picture. A three-pronged approach therefore needs to be taken by society; water needs to be effectively managed, it needs to be economically purified and it needs to be conserved.

## ACKNOWLEDGMENTS

We gratefully acknowledge the financial assistance of the Middle East Desalination Research Center (MEDRC), and Sultan Qaboos University through grant number IG/AGR/BIOR/02/04 to Mattheus F.A. Goosen. Dr. Roque-Malherbe gratefully recognizes the financial support provided by NASA through the Grant Cooperative Agreement Number NAG10-335. He would also like to acknowledge his colleagues Dr. Clyde Parrish and Mr. William del Valle for the collaboration in the permeation study.

## NOMENCLATURE

$A$	rate of loss of membrane surface area as function of time ( $\text{m}^2/\text{s}$ )
$A$	effective membrane area ( $\text{m}^2$ )
AFM	atomic force microscopy
ATR	attenuated total reflection
$B$	permeability ( $\text{mol}/\text{m s Pa}$ )
$C = 4.8 \pm 0.3$	Carman-Kozeny constant
$C_b$	bulk solute concentration ( $\text{mol}/\text{cm}^3$ )
$C_g$	gel concentration ( $\text{kmol}/\text{m}^3$ )
$C_o$	solute concentration in feed solution ( $\text{kmol}/\text{m}^3$ )
$C_p$	permeate solute concentration ( $\text{mol}/\text{cm}^3$ )
$C_w$	concentration at membrane surface ( $\text{mol}/\text{cm}^3$ )
$d_p$	average grain diameter (mm)
$d_v$	membrane pore diameter
$D$	solute diffusion coefficient ( $\text{m}^2/\text{s}$ )
FTIR	Fourier transform infrared
$G$	geometrical factor (m)
$H$	transversal dimension of channel (m)
$i$	cycle number
$J$	solvent flux across membrane ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J^*$	flux at infinite time ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_a$	average flux under steady-state conditions ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_{ai}$	solvent flux at time $a$ and in cycle $i$ ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_{\text{crit}}$	limiting or critical flux ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_{\text{lim}}$	limiting or critical flux ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_o$	solvent flux at beginning of cycle ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_s$	solute flux ( $\text{mol}/\text{cm}^2 \text{ s}$ )
$J(t_p)$	solvent flux as function of permeation time ( $\text{m}^3/\text{m}^2 \text{ s}$ )
$J_v$	permeate flux ( $\text{mol}/\text{cm}^2 \text{ s}$ )
$J$	molar gas flow ( $\text{mol}/\text{m}^2 \text{ s}$ )
$K$	hydraulic permeability of membrane to pure solvent ( $\text{m}^3/\text{N s}$ )
$k$	mass transfer coefficient
$kC_w$	adsorbed layer resistance
$L$	channel length (m)
$l$	membrane thickness (m)

$M$	molecular weight of the gaseous permeating species (kg/mol)
$m$	channel parameter
$\Delta P$	hydraulic pressure difference across membrane (cm/s)
$P$	transmembrane pressure (N/m <sup>2</sup> )
Pe	Peclet number
$\Delta P$	= $P_1 - P_2$ trans-membrane pressure (Pa)
$Q$	gas filtrate flux (m <sup>3</sup> /s)
RO	reverse osmosis
$R_m$	membrane resistance
$R$	gas constant (J/kmol K)
$Sc$	Schmidt number
$T$	temperature (K)
$t_p$	permeation time (h)
$t_c$	cleaning time (h)
UF	ultrafiltration
UTDR	ultrasonic time-domain reflectometry
$U_o$	longitudinal component of fluid velocity averaged over channel cross-section (m/s)
$V_m$	molar volume of the flowing gas

### GREEK SYMBOLS

$\varepsilon$	membrane porosity
$\Pi$	gas permeance (mol/m <sup>2</sup> s Pa)
$\rho_A$	apparent membrane density (g/cm <sup>3</sup> )
$\rho_R$	Real membrane density (g/cm <sup>3</sup> )
$\mu$	dynamic viscosity of the gas (Pa s)
$\Delta\pi(w)$	osmotic pressure at membrane surface (cm/s)
$M$	fluid viscosity
$T$	membrane lifetime (year)

## 12.1 INTRODUCTION

The use of membranes for extraction in analytical chemistry has been increasing during recent years. The main intention is to selectively extract and enrich compounds to be determined (analytes) from chemically more or less complex samples. In contrast to many technical uses of membranes, in analytical applications it is imperative to recover as efficiently as possible the extracted analytes so they can be transferred to suitable analytical instruments for the final determination in a quantitative way. Another difference from technical uses is that the volume scale is small; extracts are seldom larger than a milliliter, often only several microliters.

Membrane techniques have a number of clear advantages over other extraction techniques used in analytical chemistry. These advantages especially concern not only selectivity, enrichment power, and automation potential but also economy and occupational health aspects [1–8].

### 12.1.1 SAMPLE PREPARATION FOR ANALYSIS AND SAMPLING

In most cases of chemical analysis, some kind of sample preparation is necessary. One intention could be to bring the sample into a physical form, which is suitable for the further application of an instrumental technique for the final determination. This could be made by, for example, grinding, dissolution, combustion, filtration, etc. In many cases, for example, as a preparation for gas chromatographic analysis, analytes need to be transferred from the original matrix (e.g., water) to a solution in an organic solvent, often even involving a chemical reaction (derivatization) to improve detectability and solubility. For the determination of analytes in very low concentrations (trace analysis) it will be necessary to enrich or preconcentrate the analyte, i.e., increase its concentration to measurable levels. For analysis of complicated samples (e.g., biological or environmental origin) it is additionally crucial to perform cleanup procedures, whereby the concentrations of the analytes are increased relative to the matrix, i.e., a selective enrichment of the analytes [9–12].

Several types of sampling tasks could involve various types of extraction at the sampling site. This would be the case in integrating sampling, where the mean concentration over a period or over an area is sought, or when a speciation sampling is attempted, i.e., where the aim is to determine not only total concentrations but also equilibria (dissolved-bound, different dissociation conditions, different redox conditions, etc.).

For many of these sample preparation tasks, various types of extraction (phase-transfer) procedures are used, such as classical liquid–liquid extraction (LLE) [13–15] in different physical formats, solid-phase extraction (SPE) [16–18], solid-phase microextraction (SPME) [19,20], and other, when studying aqueous and other liquid samples. For solid samples, the classical technique is Soxhlet extraction, and there are a number of modern alternatives [21].

The conventional extraction techniques have a number of drawbacks. The most obvious one is that relatively large volumes of organic (often chlorinated) solvents are used. This aspect is easily illustrated by comparing the relevant EPA (US Environmental Protection Agency) sample preparation protocols. For example, in a generic EPA SPE procedure (Method 3535) [22], 85 mL of organic solvent is needed for extraction of 1 L of water sample (30 mL for elution, 55 mL for washings and conditioning). Method 3510, which is the corresponding LLE method, is applicable to many more analytes. It requires 180 mL of organic solvent, which is more, but not dramatically so. In both methods, the volume of the extract is reduced to 1–10 mL before analysis by evaporation. This applies to each sample, and an environmental laboratory handles thousands of samples. The use of large volumes of solvents leads to a significant expense, especially as high purity solvents are demanded, and also to concerns for occupational safety and for general environmental pollution. These techniques are also quite labor intensive and difficult to automate, why an important area of current research in analytical chemistry aims to the development of alternative extraction techniques meeting some of the disadvantages mentioned. These activities are somewhat moderated by the fact that the area of chemical analysis (especially regarding environmental and pharmaceutical applications, and also in other areas) is heavily regulated by various international and local rules, leading to that the acceptance of new technology is very slow and costly.

### 12.1.2 MEMBRANE EXTRACTION SYSTEMS

In all types of membrane extraction, the membrane separates the sample phase (often called donor or feed solution) from the acceptor or strip phase and the analyte molecules pass through the membrane from the donor to the acceptor. This process is often called pertraction (permeation–extraction). The membrane extraction techniques can be divided into porous and nonporous membrane techniques. Another distinction is between one-, two-, or three-phase membrane extraction techniques.

Typical examples of one-phase techniques are filtration and dialysis. The membrane is porous, so there is a liquid (or gas) contact through the pores between the donor and acceptor phases, which are of similar chemical composition (i.e., both are either aqueous, organic, or gaseous). There is no phase boundary, and therefore, no partition between phases. Thus, physical and not chemical properties govern the process. This review will not consider one-phase systems further. For information on dialysis, especially its analytically interesting version microdialysis, see Refs. [23,24].

Nonporous membrane techniques involve two or three phases separated by distinct phase boundaries. In three-phase membrane systems, a separate membrane phase is surrounded by two different liquid phases (donor and acceptor) forming a system with two phase-boundaries and thus two different extraction (partition) steps. These can be tailored to different types of chemical reactions, leading to a high degree of selectivity. The membrane phase can be a liquid, a polymer, or a gas, and the donor and acceptor phases can be either gas or liquid (aqueous or organic). Liquid membrane phases are often arranged in the pores of a porous hydrophobic membrane support material, which leads to a convenient experimental system, termed supported liquid membrane (SLM). There are several other ways to arrange a liquid membrane phase between two aqueous phases as described below.

In two-phase membrane systems, one of the surrounding phases is the same as the membrane phase, so there could be, for example, an organic solvent both in the membrane pores and in the acceptor, while the donor is aqueous or gaseous. There is only one phase boundary, and consequently, only one partition equilibrium. This technique is chemically analogous to LLE in separation funnels.

### 12.1.3 MEMBRANE DEVICES FOR SAMPLE PREPARATION

#### 12.1.3.1 Flat-Sheet Devices

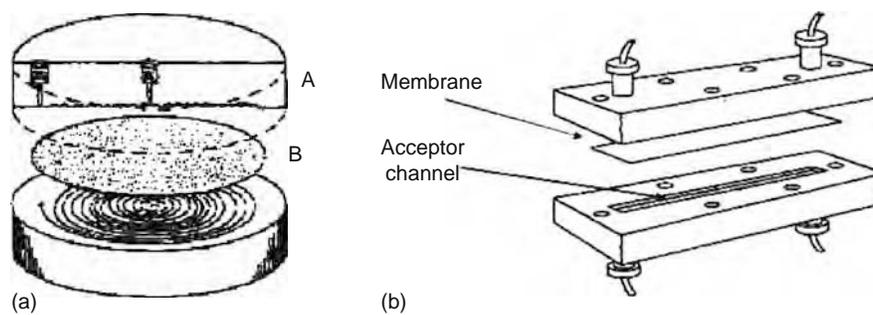

Classically, flat-sheet porous PTFE or polypropylene membranes are used as support for the membrane liquid and mounted in holders (cells, contactors) permitting one flow channel on each side of the membrane [1,3,6,8,25]. See Figure 12.1. Such membrane units are typically operated in flow systems and in principle applicable to all versions of membrane extraction for analytical sample preparation or sampling. Such a setup can be easily interfaced with different analytical instruments, such as HPLC and various spectrometric instruments, and thereby provides good possibilities for automated operation. Drawbacks of this type of devices are relatively large costs and limited availability, as well as some carryover and memory problems as the membrane units are utilized many times, necessitating cleaning between each extraction.

#### 12.1.3.2 Hollow Fiber Devices

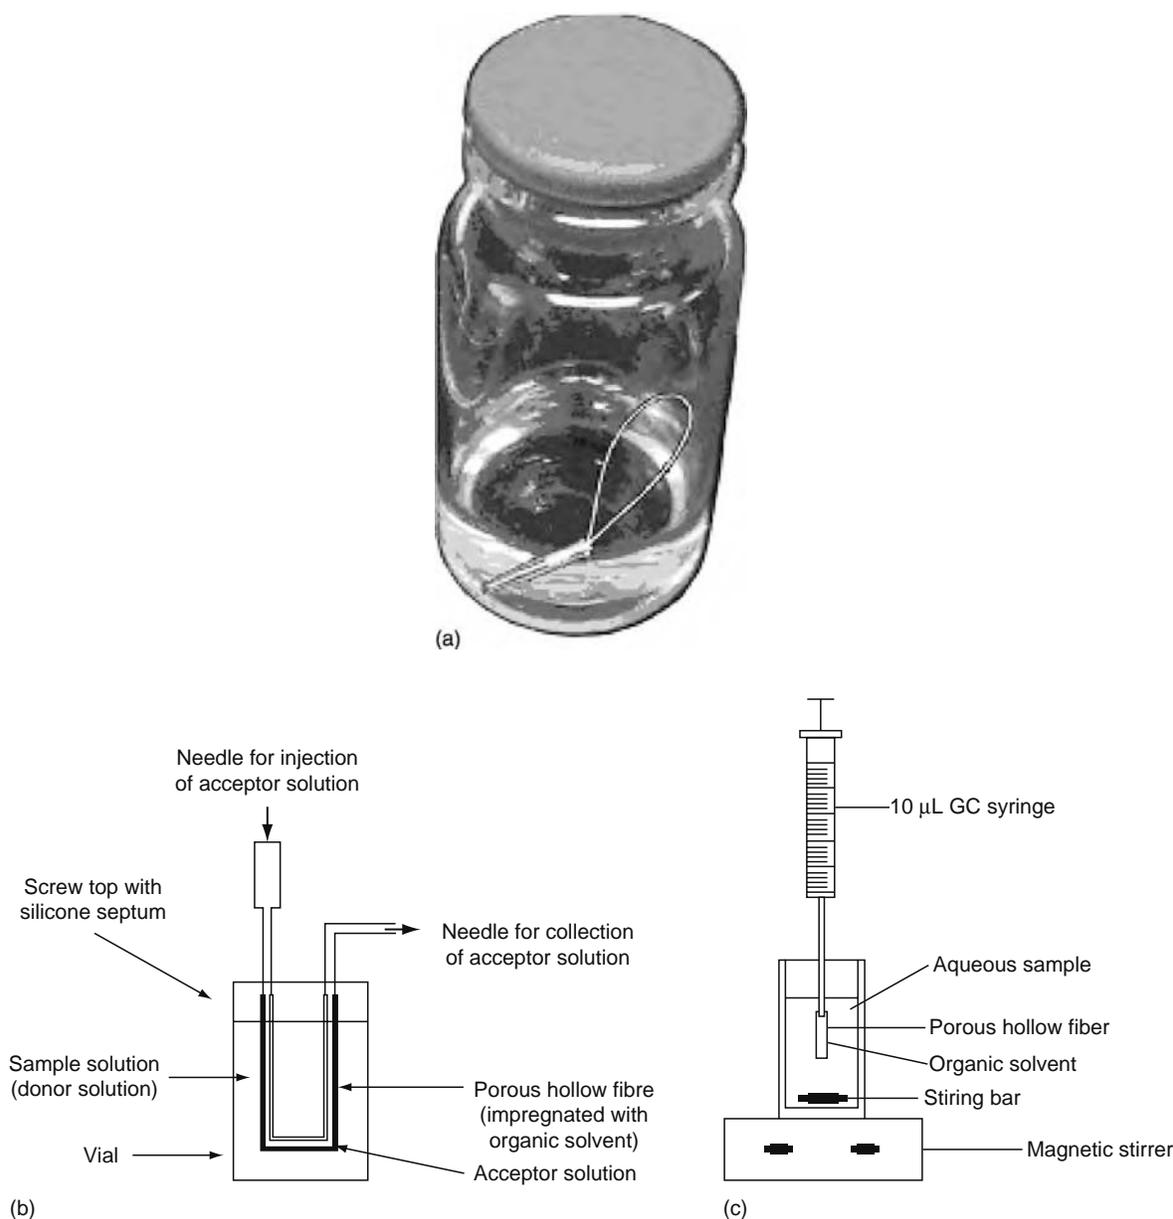

In another type of membrane extraction devices, porous polypropylene hollow fibers are used, often in a disposable way, which minimizes carryover problems and reduces costs [26–33]. On the other hand, manual manipulations are needed, limiting the possibility for automation. With these devices, the extraction can be carried out in a static mode, either in large sample volumes, where the extraction is not intended to be complete, or in small volumes aiming for complete extraction. Usually, stirring is applied to increase the speed of mass transfer. Some typical practical arrangements are shown in Figure 12.2. This type of SLM extraction is often called hollow fiber liquid phase microextraction, or three-phase liquid phase microextraction or two-phase liquid phase microextraction but the terminology in this active field of research has not been settled. Also hollow fibers can be connected in flow systems [34,35].

### 12.1.4 EQUILIBRIUM AND TRAPPING

After an extraction system has been left for enough long time, equilibrium between the phases is reached and mass transfer from the donor to the acceptor has stopped. This is the natural end point for the extraction in many cases. In the majority of

**FIGURE 12.1** Flat-membrane modules for membrane extraction in flow systems. (a) Spiral-channel membrane module with 1 mL channel volume (A, blocks of inert material; B, membrane). Chem.*, 77, 4800, 2005.) (b) Liquid-phase microextraction after Pedersen-Bjergaard and Rasmussen. (From Grønhaug Halvorsen, T., Pedersen-Bjergaard, S., Reubsaet, J.L.E., and Rasmussen, K.E., *J. Sep. Sci.*, 24, 615, 2001. With permission.) (c) Syringe-based hollow fiber LPME. (From Zhao, L. and Lee, H.K., *Anal. Chem.*, 74, 2486, 2002. Copyright 2002 American Chemical Society. With permission.)

applications, however, the extraction is stopped well before the equilibrium is attained, as this often results in procedures that are more efficient in terms of time and convenience. In analytical chemistry, a usual aim of the sample preparation is to transfer (recover) as much of the analyte as possible from the donor to the acceptor to maximize sensitivity and minimize detection limits. This recovery can be improved in principally two ways: the acceptor can be continuously changed, or continuously flow past the membrane, so extracted molecules are removed from the membrane surface by convection. This typically leads to a dilution of the analyte. Alternatively, and more efficiently, the analyte molecules can be trapped in a static acceptor by a chemical reaction (e.g., dissociation) or by exploiting a high distribution coefficient. This usually leads to enrichment, and with an efficient trapping reaction there is a potential of obtaining very high enrichment factors.

To improve the overall amount of analyte that is extracted, a flowing donor is often used; i.e., the sample is pumped past the donor side of the membrane in a dynamic flow system. Also static systems with a stagnant donor are common, often with convective mixing by stirring.

This chapter mainly covers extraction systems with liquid membrane phases and trapping in the acceptor. Two- and three-phase systems are compared, as well as dynamic and static systems and flat versus hollow-fiber membrane materials. These types of systems have been successfully applied to a number of analyte and sample types and can be important alternatives to more orthodox approaches to sample preparation.

## 12.2 VARIANTS OF MEMBRANE EXTRACTION

A number of nonporous membrane techniques with different phase systems have been suggested for sample preparation in analytical chemistry. The main versions are summarized in Table 12.1 and described in the following sections.

### 12.2.1 LIQUID MEMBRANE EXTRACTION TECHNIQUES

In all liquid membrane extraction techniques, the membrane is an organic liquid, which is in contact with the aqueous sample. Analytes are extracted either by simple partitioning of uncharged species into the organic phase or by the action of some extractant, a compound present in the membrane liquid which can form complexes with the analyte, thereby facilitating its transport into the membrane liquid. So far, this is in principle the same as classical LLE. The difference between the various liquid membrane extraction techniques refers mainly to the acceptor side of the membrane.

#### 12.2.1.1 Three-Phase Liquid Membrane Extraction

With three-phase liquid membrane extraction techniques, there is a stagnant aqueous acceptor phase, constantly in contact with the liquid membrane, and the analytes are, after travelling through the membrane, transferred to the aqueous acceptor phase. The composition of the acceptor phase is such that the analyte molecules, after entering the acceptor phase become non-extractable, for example by pH changes (for acids or bases) or by some complexation reactions. This is referred to as trapping and it results in a transport of analyte molecules from the donor to the acceptor phase, which after the extraction can be transferred to an analytical instrument, either manually or online by a flow system. Trapping is crucial for the success of the three-phase liquid membrane extraction. By means of suitably selected acceptor conditions, it is possible to tune the mass transfer process and to obtain the desired selectivity and degree of enrichment for a number of useful applications.

##### 12.2.1.1.1 Supported Liquid Membrane Extraction

In SLM extraction, the most widely applied type of three-phase membrane extraction, the membrane consists of an organic solvent, which is held by capillary forces in the pores of a hydrophobic porous membrane supporting the membrane liquid. Such membrane support can be either flat porous PTFE or polypropylene membrane sheet or porous polypropylene hollow fibers. Typical solvents are long-chain hydrocarbons like *n*-undecane or kerosene and more polar compounds like dihexyl ether, dioctyl phosphate, and others. Various additives can increase the efficiency of extraction considerably. The stability of the membrane depends on the solubility and volatility of the organic liquids, and it is generally possible to obtain membrane preparations that are stable up to several weeks.

**TABLE 12.1**  
**Different Types of Membrane Extraction**

Generic Name	Names Used	Abbreviation	References <sup>a</sup>
Three-phase liquid membrane extraction aq/org/aq	Supported liquid membrane extraction	SLM	[6,85]

### 12.2.1.1.2 *Nonsupported Liquid Membrane Extraction*

In addition to SLM, which is the most commonly used three-phase extraction principle, at least in analytical chemistry, also other ways of placing an organic phase between two aqueous phases are known. In the classical bulk liquid membrane (BLM) setups, U-tubes or similar devices are used to confine bulk volumes of organic liquids between two aqueous phases. This type of devices is very little used for sample preparation in analytical chemistry, as the extraction process becomes slow and the enrichment factors possible are very limited.

Some devices, which permit the stacking of an aqueous acceptor phase above an organic liquid above an aqueous donor phase, have been described [36–38]. Such systems are of course inherently physically unstable, especially when stirring, but some success with such principles has been shown.

A liquid membrane configuration, which is much used for technical applications, is the emulsion liquid membrane (ELM) systems where the acceptor phase is dispersed as a colloid phase, each colloid drop surrounded by a thin organic, surface active phase. This principle does not seem to have been used for analytical sample preparation, probably due to the difficulty of quantitatively recovering the dispersed acceptor phase.

### 12.2.1.2 **Two-Phase Liquid Membrane Extraction Systems**

Two-phase liquid membrane extraction systems can be seen as a variant of SLM, where both the membrane (located in the pores of a hydrophobic porous membrane support) and the acceptor phases consist of an organic solvent. This is mainly suitable for hydrophobic analytes that are non-dissociable and non-charged. These compounds are easily extracted from water to an organic solvent, but they cannot be back-extracted into a second aqueous phase as required by the SLM approach.

This is chemically the same principle as for conventional LLE, but can be performed in a flow system, which permits easy automation and interfacing to analytical instruments. The technique is most easily interfaced to gas chromatography (GC) or to normal-phase high performance liquid chromatography (NP-HPLC), as the extract ends up in an organic phase. In principle, the membrane could also be hydrophilic, which would lead to an aqueous phase in the membrane pores. This seems not yet to have been tried for analytical purposes.

LLE in a flow system (in the form of flow injection analysis) has been described many times as reviewed by Valcárcel and Luque de Casto [39], but then the organic and aqueous phases are mixed in the same flow channel and later separated. The practical problems with the phase separation seem to have prevented this technique to be widely used. Applying a membrane, the phases are never mixed and all mass transfer between the phases takes place at the membrane surface.

As with three-phase membrane extraction, it is also possible here to work either with flat membranes, or with hollow-fiber membranes. In the first case, the technique is usually called microporous membrane liquid–liquid extraction (MMLLE), a name originating from Cussler [40]. With hollow fibers, it can be called two-phase liquid phase microextraction.

With two-phase liquid membrane extraction as with classical LLE, the extraction efficiency is limited by the partition coefficient. If this is very high, it is possible to work with a stagnant acceptor and still obtain a considerable enrichment into a small extract volume. With smaller partition coefficients, it might be necessary to arrange the acceptor phase to move with a slow flow rate to successively remove the extracted analyte and maintain the diffusion through the membrane. This will then lead to a lower degree of enrichment. The situation is similar to that for dialysis, and various focusing approaches can be applied to improve it, such as an SPE column or a retention gap.

## 12.2.2 **SOLID (POLYMERIC) MEMBRANE EXTRACTION TECHNIQUES**

A number of applications with polymeric membranes have been described. The most commonly used membrane material is silicon rubber or polyethylene. The possibility for both aq/polymer/aq extraction (including trapping in the acceptor, very similar to SLM extraction) and also, e.g., aq/polymer/org extraction (similar to MMLLE) has been demonstrated.

Melcher [41–43] first described both these principles in cylindrical configurations, utilizing thin silicone tubes in flow systems. More recently, Hauser et al [44] introduced the principle of MASE (membrane-assisted solvent extraction), which comprises a polypropylene bag in an autosampler vial with an organic solvent inside the bag. This device is commercialized by Gerstel (Mülheim an der Ruhr, Germany).

In the aq/polymer/org situation, the organic solvent typically penetrates the polymer causing it to swell considerably, and the situation is very similar to that of MMLLE. With a fixed composition of the membrane, the possibilities for chemical tuning (such as application of carriers) of the separation process are greatly reduced compared to SLM extraction or MMLLE. Also, as diffusion coefficients in polymers are lower than in liquids, the mass transfer is slower, leading to slower extractions. On the other hand, as the membrane is virtually insoluble, any combination of aqueous and organic liquids can be used, and the entire system becomes very stable.

## 12.3 THEORY AND PRINCIPLES OF MEMBRANE EXTRACTION

### 12.3.1 PRINCIPLES OF SLM

An SLM extraction can be seen as a combination of extraction into an organic solvent followed by a back-extraction into a second aqueous phase. However, as these two extraction steps occur simultaneously, the mass transfer kinetics will be different, and generally more efficient, compared to the situation when the steps are performed in sequence in separation funnels. The general mass transfer theory for SLM extraction in flow systems has been described in detail [45], with some additional aspects described more recently [46].

The rate of mass transfer from donor to acceptor (in any membrane extraction system) is proportional to the concentration difference,  $\Delta C$ , of the diffusing species over the membrane, which can be written

$$\Delta C = C_D - \frac{1}{D} C_A \quad (12.1)$$

where

$C_D$  and  $C_A$  are the total concentrations in the donor and acceptor phase, respectively  
 $D$  is the distribution constant between the acceptor and the donor phases

In SLM,  $D$  is given by the following expression:

$$D = \frac{C_A}{C_D} = \frac{\alpha_D K_D}{\alpha_A K_A} \quad (12.2)$$

where

$\alpha_D$  and  $\alpha_A$  are the fractions of the analytes that are in extractable (usually uncharged) form in the indicated phase  
 $K_A$  and  $K_D$  are the acceptor/membrane and donor/membrane partition coefficients (i.e., pertaining to the uncharged form only), respectively

Note that in many cases it will be a good approximation that  $K_A = K_D$  as both the donor and acceptor phases are aqueous, and deviations from this equality will be mainly due to ionic strength effects. Thus, the main influence in determining the value of  $D$  will be shown by the  $\alpha$ -values, which, for example, for acids or bases can easily be varied over many orders of magnitude by selecting suitable pH values. Often, the extraction conditions are setup so that  $\alpha_D$  is close to 1 and  $\alpha_A$  is a very small value.  $C_A$  is zero from the beginning of the extraction and increases successively, usually to values well over  $C_D$ . The maximum enrichment factor, which is reached when there is a thermodynamic equilibrium between all phases, is equal to  $D$  as in Equation 12.2. In contrast to the conditions for classical LLE and also MMLLE, high partition coefficients are not essential for high enrichment factors in SLM extraction.

The rate at which the equilibrium conditions are approached depends on many parameters, as detailed elsewhere [45] for systems with flowing donor and stagnant acceptor. Briefly, two situations can be distinguished: membrane-controlled extraction and donor-controlled extraction. In the first case, the rate-limiting step is the diffusion of the analyte compound through the membrane. The mass transfer coefficient  $k_M$  is then proportional to  $K_D \cdot D_M/h_M$ , where  $D_M$  is the diffusion coefficient in the membrane and  $h_M$  is the thickness of the membrane.

With donor-controlled conditions, typically, a considerably higher mass transfer rate can be obtained. It is then limited by the diffusion in the donor phase and thus depends on the diffusion coefficient in the donor phase,  $D_D$ , and on the donor convection (flow, stirring, etc.) conditions. As a rule of thumb, the donor-controlled extraction conditions prevail when  $K_D$  is larger than about 10, while the mass transfer is mainly membrane-controlled when  $K_D < 1$ . It is found that the value of the partition coefficient has no large influence on the efficiency of extraction or the enrichment factors that can be obtained, as long as it is reasonably large. On the other hand, the rate at which equilibrium is reached will be influenced by the partition coefficients. Further, there are observations that too large partition coefficients are not favorable, as the transfer of analyte out of the membrane into the acceptor phase in those cases may become less efficient.

### 12.3.2 CHEMISTRY OF SLM EXTRACTION

For SLM extraction a number of chemical principles can be used, which can be summarized according to Table 12.2 and detailed below.

**TABLE 12.2**  
**Schematic Overview of Different Chemical Principles for Extraction and Trapping Used for SLM Extraction**

Analytes	Donor	Membrane	Acceptor	Transported Species	Trapping	References
<i>Simple permeation</i>						
Acids	Acidic	Org (+TOPO)	Basic	Neutral	Anions	[6,88]
Bases	Basic	Org	Acidic	Neutral	Cations	[6]
<i>Carrier-mediated transport</i>						
Metal ions	8-Hydroxy-quinoline	Org	DTPA	Complexes	Charged complexes	[50]
Metal ions, amino acids	Acidic, pH = 3	DEHPA	Acidic, pH = 0	Complexes	Counter transport of H+	[57]
Amino acids, amino phosphonates	Basic	Triocylmethyl ammonium	Acidic, chloride	Ion pairs	Cations	[52,89–91]
Amino acids	Basic	Pd-complex	Acid	Complexes	Cations	[92,93]
Sugars, diol-containing compounds	Neutral	Boronic acid carrier	Acid	Covalently bound complexes	Protonation of carrier	[94,95]
Anionic surfactants	Acidic + amine	Org	Basic	Ion pairs	Deprotonation of amine carrier	[59]
<i>Immunological trapping</i>						
Triazine herbicides	Neutral	Org	Atrazine antibodies	Permeation	Immunological as antigen–antibody complex	[60]

Note: Abbreviations: TOPO, trioctylphosphine oxide; DTPA, diethylenetriaminepentaacetic acid; DEHPA, diethylhexylphosphoric acid.

### 12.3.2.1 Simple Permeation—Acids and Bases

Many applications of SLM extraction in analytical chemistry concern the extraction of acids or bases. Here, the basic principle is that uncharged species can be extracted from an aqueous phase into an organic solvent phase, while the charged species stay in the aqueous phase. This principle is well known from classical LLE, where it is a common practice to extract acids from acidic samples, and back-extract the acids into a second alkaline aqueous phase, using solvents like hexane, diethyl ether, etc.

For an acidic analyte HA, the alpha-factors mentioned above will take the following form:

$$\alpha = \frac{[\text{AH}]}{[\text{A}^-][\text{AH}]} = \frac{1}{1 + 10^{(\text{pH} - \text{p}K_a)}} \quad (12.3)$$

and for a basic analyte B

$$\alpha = \frac{[\text{B}]}{[\text{B}][\text{BH}^+]} = \frac{1}{1 + 10^{-(\text{pH} - \text{p}K_a)}} \quad (12.4)$$

where

$\text{p}K_a$  refers to the dissociation constant

$\text{pH}$  refers to either the donor or acceptor phase

From Equations 12.2 through 12.4, the expression for the overall distribution constant at equilibrium for the extraction from the donor to the acceptor is obtained:

$$D = \frac{C_A}{C_D} = \frac{\alpha_D K_D}{\alpha_A K_A} = \frac{(1 + 10^{s(\text{pH}_A - \text{p}K_a)})}{1 + 10^{s(\text{pH}_D - \text{p}K_a)}} \frac{K_D}{K_A} \quad (12.5)$$

where  $s = 1$  for acids and  $s = -1$  for bases, and as mentioned above, usually  $K_A \approx K_D$ .

Knowing the  $\text{p}K_a$  and the  $\text{pH}$  of the phases, it is easy to calculate the overall distribution constant and thus the maximum enrichment factor possible for SLM extraction of acids or bases with simple permeation.

### 12.3.2.2 Carrier-Mediated Transport—Metals and Organic Ions

Ion-pairing or chelating reagents can be added to the donor phase, which permits SLM extraction of various metal ions. Different carrier molecules or ions can be incorporated in the membrane phase to enhance selectivity and mass transfer. Various trapping reagents in the acceptor phase prevent analytes to be extracted back into the membrane. There are several reviews in this field [47–49].

As an analytical example of an addition of a reagent to the donor phase, extraction of metals from solutions containing a complex former as 8-hydroxyquinoline can be mentioned. This reagent forms extractable complexes with many metals [50]. See Figure 12.3a. The complex will be transported through the membrane and the extracted analyte is trapped in the acceptor by another ligand, in this case DTPA (diethylenetriaminepentaacetic acid), which forms a stronger complex which is charged and therefore non-extractable.

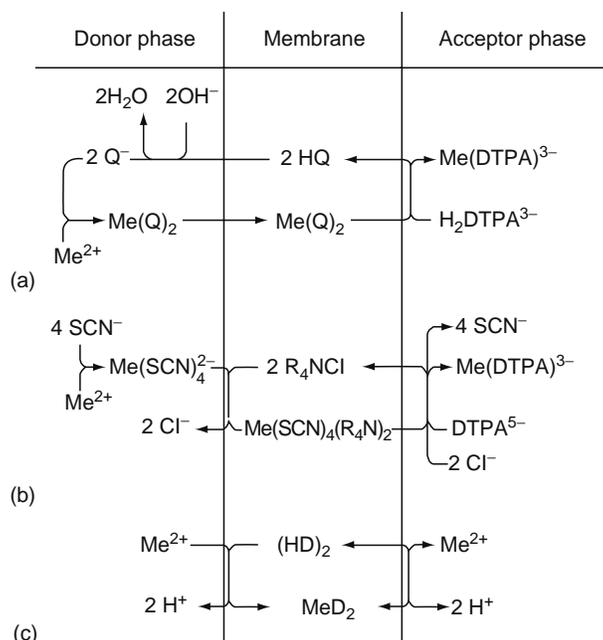

A carrier can be added to the membrane phase in several ways. A common compound is Aliquat-336 (methyltriocetyl-ammonium chloride). This is a tertiary ammonium ion, i.e., permanently positively charged in ion pair with chloride and can thus be added to a suitable membrane solvent. After addition of thiocyanate ions to the donor, a negatively charged metal-thiocyanate complex is formed in the donor and can be extracted as ion pair with the Aliquat-336 cation. It was used for extraction of Cu, Cd, Co, Zn [49] and for chromate [51]. The metal ion is subsequently trapped in the acceptor using DTPA as described above and shown in Figure 12.3b.

Analogous principles have been used to extract organic compounds, for example, amino acids [52] and peptides [53,54]. In a basic donor, the extracted compounds are anionic, and thus easily transported through the membrane by the cationic carrier to the acidic acceptor, where the analytes become cationic, and thus non-extractable.

Another commonly used extraction reagent for metal ions is diethylhexyl phosphoric acid (DEHPA) [55,56]. See Figure 12.3c. In this case a pH gradient must exist over the membrane, so the acceptor is kept more acidic than the donor (typically  $\text{pH} \approx 1$  and  $\text{pH} \approx 3$ , respectively). Speciation of different chromium species (chromate and chromium ion) has been performed by the combination of two membrane extraction systems, one working with DEHPA for extraction of  $\text{Cr}^{3+}$  and the other with Aliquat-336 for extraction of the chromate anions [51]. Using the same principles, also organic compounds, such as amino acids [57] and polyamines [58], can be extracted.

### 12.3.3 ANALYTE TRAPPING IN SLM

To reach a concentration enrichment using SLM for the purpose of sample pre-treatment for chemical analysis, the concept of trapping is imperative. It is necessary that the analyte, which has reached the acceptor phase, is in one way or the other

**FIGURE 12.3** Membrane extraction schemes of metal ions (Me). HQ, 8-hydroxyquinoline;  $\text{DTPA}^{5-}$ , diethylenetriaminepentaacetic acid anion;  $\text{R}_4\text{N}^+$ , methyltriocetyl ammonium cation; HD, diethylhexyl phosphoric acid. For a, b, and c, see the text.

prevented from diffusing back into the donor, so that a steady mass transfer of analyte, against a gradient of total analyte concentration, is maintained for sufficient time to permit a substantial concentration enrichment factor.

### 12.3.3.1 Direct Trapping

The simplest principle for analyte trapping was described above in Section 12.3.3. To perform enrichment of an acidic compound, the pH of the acceptor is held enough alkaline, so the main fraction of the acidic analyte becomes charged, and thus non-extractable in the acceptor. This is analogous with the principle of back-extraction in LLE, where an organic extract of an acidified sample is extracted with a second aqueous phase, to isolate acidic compounds. The principle of this type of direct trapping is described by Equations 12.3 through 12.5, showing the influence of pH on the extractability of acidic (or basic) compounds. If the donor pH is selected less than or equal to the  $pK_a$  and the acceptor  $pH > pK_a + 3.3$ , the distribution coefficient between acceptor and donor at equilibrium (Equation 12.5) will be about 2000, promising potentially very high concentration enrichment factors. This is termed “complete trapping.”

Extracting an acid from an acidic donor to a basic acceptor brings about a cotransport of protons through the membrane, eventually neutralizing the pH gradient, why it is imperative for good success that the buffer capacity of the acceptor is sufficient. Conversely, the extraction of a basic compound from a basic donor to an acidic acceptor will transport protons in the opposite direction.

Other variations of the principle to render the analyte non-extractable in the acceptor involve the use of complexing agents. These form charged complexes in the acceptor, preventing back-extraction. The use of DTPA for trapping of metal ions, as described above in Section 12.3.3, is a good example on this.

### 12.3.3.2 Indirect Trapping

In systems employing carrier-mediated transport of the analyte through the membrane, the analyte trapping can be made in a somewhat different way, where the transporting properties of the carrier are influenced, so it can transport the analyte from the donor to the acceptor, but not the other way. An example is the use of DEHPA, for metal extraction, where the carrier is anionic at donor conditions, permitting transport to the strongly acidic acceptor where the carrier is neutralized, preventing back-extraction of the analyte. Here is a counter-transport of protons because the pH gradient drives the extraction, while the analyte is in the same form both in the donor and in the acceptor.

There are other versions of a similar principle. For the extraction of anionic surfactants [59], which are permanently charged, trihexyl amine was used as a carrier. The carrier is added to the sample in the donor. In the acidic donor this amine is charged, and can form ion-pair with the analytes, while in the alkaline acceptor, the amine is neutralized, thus killing the ion-pair.

### 12.3.3.3 Immunological Trapping

To utilize the high degree of selectivity possible with biological recognition in sample preparation, SLM extraction was combined with immunologic recognition, both by using antibodies as trapping reagent in the acceptor, and exploiting the antibody–antigen complex in a flow immunoassay, both for successful determination of nitrophenol [60] and atrazine [61]. In a recent development utilizing magnetic beads with antibodies, simazine was determined in low concentrations [62].

## 12.3.4 MASS TRANSFER IN MMLLE

For two-phase liquid membrane extraction, (MMLLE), the basic principles are more simple than those for SLM, as there is only one phase boundary involved in the extraction, usually from an aqueous to an organic phase, which is chemically equivalent to LLE in a separatory funnel, etc. The extraction is driven by the difference in chemical potential of the analytes in organic solvent and in aqueous solution, which is described as a partition coefficient. In many cases, the octanol–water partition coefficient ( $\log K_{OW}$ ) is considered as estimates for the partition coefficient in MMLLE and LLE, even if the organic solvents used usually are other than octanol. The techniques work best for relatively nonpolar compounds, having values of  $\log K_{OW} > 3$ .

With obvious modifications, Equation 12.1 is valid also for MMLLE. The definition of the relevant distribution coefficient is different. For MMLLE it is

$$D = \frac{C_A}{C_D} = \alpha_D K_D \quad (12.6)$$

Here,  $K_D$  is the partition coefficient between the organic acceptor phase and the aqueous donor (sample) phase. For acidic or basic compounds  $\alpha_D$  is given by Equation 12.3 or 12.4, while for non-chargeable compounds  $\alpha_D = 1$ . Thus in MMLLE, the organic/aqueous partition coefficient directly governs the extraction.

### 12.3.5 DIFFERENCES BETWEEN MMLLE AND SLM

The MMLLE technique can be seen as a complement to the SLM extraction, permitting membrane-based extraction to be extended to further classes of compounds. Compared with SLM, MMLLE has the following characteristics:

- It is applicable to hydrophobic, preferably uncharged compounds, i.e., those that cannot be extracted with SLM.
- Maximum concentration enrichment possible is limited by the partition coefficient (Equation 12.11), whereas in SLM it is dependent on the degree of trapping (Equation 12.2), which can be influenced by controlling the pH of the different phases. Therefore, SLM provides more degrees of freedom by which the conditions of extraction can be tuned.
- Extract ends up in the organic solvent, not in water. Thus MMLLE is more easily interfaced to gas chromatography and NP-HPLC than to SLM, which is most compatible with reversed-phase HPLC.
- Hardware is identical or similar, so the possibilities for automation should be similar, considering the point above.

### 12.3.6 CONCENTRATION ENRICHMENT

One of the main purposes of membrane extraction in sample preparation is to enrich the analyte, i.e., to increase the concentration of the analyte to permit determination of low concentrations. Plotting the concentration of analyte in the acceptor ( $C_A$ ) either directly as determined by analysis of the acceptor phase or as a concentration enrichment factor  $E_e$  ( $C_A/C_S$ —where  $C_S$  is the initial concentration in the sample) versus time will typically produce a curve which initially raises approximately linearly and asymptotically eventually reaches a steady equilibrium value. See Figure 12.4 [46].

Assuming that the rate of mass transfer is proportional to the concentration difference over the membrane according to Equation 12.1 and noting that in static extraction, the concentration in the donor phase  $C_D$  decreases as analyte is transferred over the membrane. We get the following differential equation:

$$\frac{\partial C_A}{\partial t} = k \left( C_S - \left( \frac{V_A}{V_S} \frac{1}{D} \right) C_A \right) \quad (12.7)$$

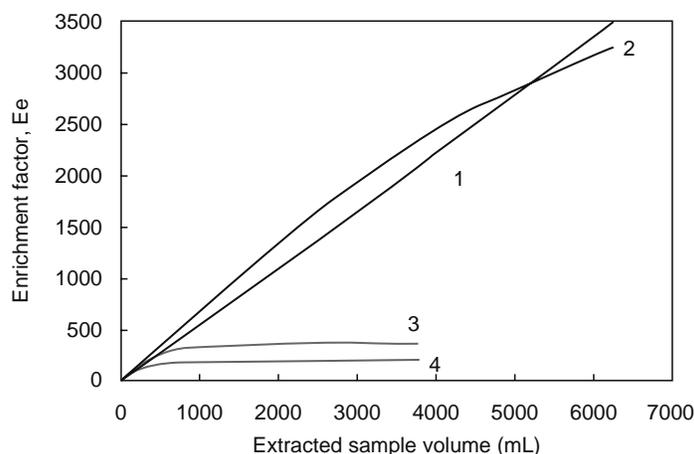

where

$V_A$  and  $V_S$  are the volumes of the acceptor (strip) phase and the extracted sample, respectively

$C_S$  is the initial concentration in the sample ( $C_S V_S = C_D V_S + C_A V_A$ )

$D$  is the equilibrium distribution coefficient (see Equations 12.2, 12.5, and 12.6)

$k$  is a rate constant

**FIGURE 12.4** Enrichment factors for various aniline compounds with different  $pK_a$  values and  $pH_A = 0$  ( $\alpha_D = 1$ ). (From Chimuka, L., Megersa, N., Norberg, J., Mathiasson, L., and Jönsson, J.Å., *Anal. Chem.*, 70, 3906, 1998. With permission.)

S.No.	Compound	$pK_a$	$\alpha_A$	$D$
1	Aniline	4.6	0.000025	40,000
2	3-Cl-4-Me-aniline	4.0	0.0001	10,000
3	3,5-di Cl-aniline	2.5	0.003	330
4	3-Me-5-nitroaniline	2.3	0.005	200

The general solution expressed as a concentration enrichment factor  $E_e$  is

$$E_e = \frac{C_A}{C_S} = \frac{1}{\left(\frac{V_A}{V_S} + \frac{1}{D}\right)} \left(1 - \exp\left[-k\left(\frac{V_A}{V_S} + \frac{1}{D}\right)t\right]\right) \quad (12.8)$$

The rate of mass transfer through the membrane is proportional to the gradient of this curve, and thus decreases from an initial value to practically zero. The concentration enrichment factor value at equilibrium will be

$$E_{e_{eq}} = \frac{1}{\left(\frac{V_A}{V_S} + \frac{1}{D}\right)} \quad (12.9)$$

Equations 12.7 through 12.9 are basically valid for static extraction. For extraction in a flow system with flowing donor and stagnant acceptor, the phase ratio ( $V_A/V_S$ ) is zero, as depletion of the sample is not possible.

There are several limiting cases for Equations 12.8 and 12.9.

1. With a large equilibrium distribution coefficient  $D$  (complete trapping) and a large phase ratio,  $E_e$  will increase linearly up to large values. In Figure 12.4, which refers to an SLM flow system experiment,  $D$  in curve 1 is approximately 10,000 and the enrichment factor is linear at least up to at least 3000 times. In many cases, especially in flow systems, the extraction is not allowed to go to equilibrium, and an extraction efficiency  $E$  is defined as the fraction of the total amount of analyte that is transferred to the acceptor. Thus

$$E = \frac{C_A}{C_S} \frac{V_A}{V_S}; \quad E_e = E \frac{V_S}{V_A} \quad (12.10)$$

The extraction efficiency is related to the slope of the extraction curve, so if the extraction is linear,  $E$  is constant and less than 100%. By careful calibration and keeping the experimental parameters constant so that the system is kinetically stable, repeatable values for  $E_e$  and  $E$  can be obtained. This will give reproducible quantitative results and most of the applications of membrane extraction to practical analyses are in fact based on this principle.

2. With a finite sample volume in static extraction mode under complete trapping conditions, the sample will eventually be depleted with regard to analyte, so a decrease of mass transfer is due to decrease of analyte concentration and the equilibrium occurs after virtually all analyte has been transferred to the acceptor. Equation 12.9 then leads to

$$E_{e_{eq}} \frac{V_S}{V_A}; \quad C_A = C_S \frac{V_S}{V_A}, \quad (12.11)$$

i.e., the enrichment factor is determined by the phase ratio.

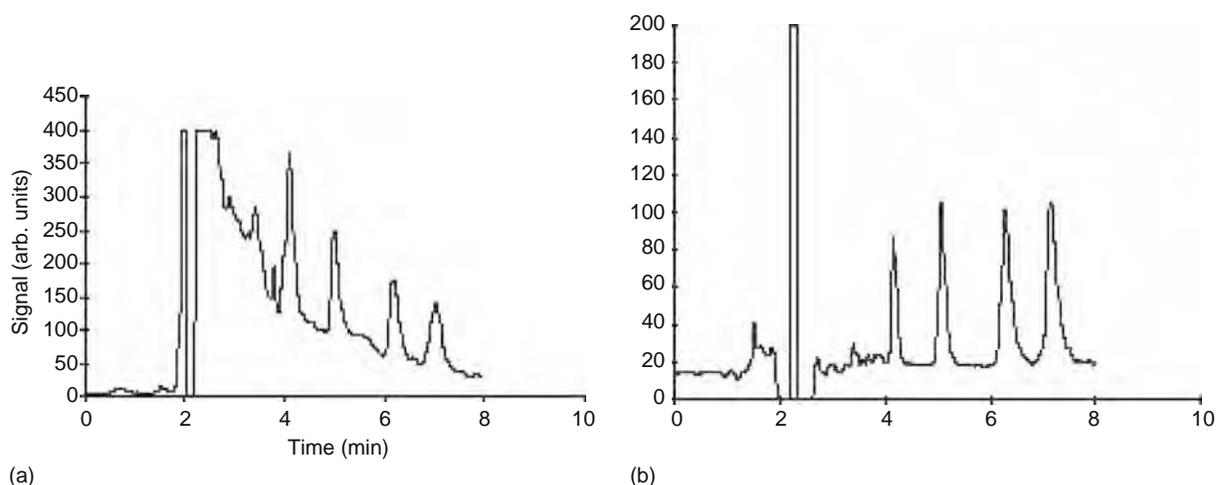

Thus, if the extraction is continued until equilibrium so that the sample is totally depleted with analyte, very simple and straightforward calculations of the enrichment factor are possible, according to Equation 12.11, which contains no other parameters than the phase volumes. This can be the basis for accurate quantitative determinations.

3. The third limiting case of Equation 12.9 is the situation where equilibrium is attained without depletion of the analyte in the sample. It is treated below in Section 12.3.8.

### 12.3.7 SELECTIVITY

To obtain a high selectivity, i.e., discrimination between the analytes and various unwanted matrix compounds, membrane extraction has a clear advantage over other sample preparation techniques, as all compounds that reach the analytical instrument must travel through the membrane. There is no direct connection and possibility for transferring compounds into the analytical instrument in other ways. This is not the case with other extraction techniques. With SPE, SPME, etc., there is a definite possibility that matrix components are adsorbed on the sorbing phase and subsequently being eluted into the extract. With LLE, such a transfer is less probable and it is generally considered that extracts after LLE are cleaner. The possible and common problem of the formation of emulsions at the phase interface with LLE, which is avoided with all types of membrane extraction, is a source of contamination across the phase border.

Further, with SLM extraction, the pH of the donor solution and the acceptor phase can easily be fine-tuned to obtain extraction which is selective for certain groups of compounds, as described above. Alternatively, a carrier can be added in the membrane to increase the selectivity and mass transfer of the compounds of interest. When the primary aim of adding a carrier is to increase the mass transfer of the analytes by analyte-carrier interactions in the membrane, it is important to choose other conditions carefully so that selectivity is still retained.

**FIGURE 12.5** Chromatograms (LC-UV) of methoxy-*s*-triazine herbicides (a) SPE of spiked river water (1.0 mg/L of each analyte) (b) SLM extraction of spiked river water (0.5 mg/L of each analyte). Peaks: 1 simetone; 2 atratone; 3 secbumetone; 4 terbumetone. (From Megersa, N., Solomon, T., and Jönsson, J.Å., *J. Chromatogr. A*, 830, 203, 1999. With permission.)

Membrane extraction is especially effective in discriminating toward macromolecules. In environmental analysis, macromolecular humic acids are ubiquitous and usually very efficiently removed. Megersa et al. [63] compared SLM and SPE of some triazine herbicides spiked in river water. As is seen from Figure 12.5, the difference is dramatic. Also, there are many examples of how various drugs can be determined in blood plasma and also urine without matrix interferences [25,64].

### 12.3.8 EQUILIBRIUM EXTRACTION

A somewhat different approach to analytical extraction involves selection of a relatively low value of  $D$  and a virtually infinite phase ratio ( $V_S \gg V_A$ ). With these conditions Equation 12.9 reduces to

$$Ee_{eq} = D \quad (12.12)$$

This is essentially the same as Equation 12.2. Curves 3 and 4 (and to some extent curve 2) in Figure 12.4 are illustrations to this. Experimentally, enrichment factors at equilibrium agree reasonably with calculated (Equation 12.5) values of  $D$  [32,46]. The concentration of analyte in the sample will not be influenced by the extraction, and this permits extraction and sampling without influencing speciation conditions in the sample. This is the basis for a novel sampling technique, called ESTM (equilibrium sampling through membranes) which is currently developed for the measurement of freely dissolved fractions of environmental pollutants (as distinguished from total concentrations). This parameter is of environmental interest, as it describes transport processes and biological activities better than total concentrations [65]. The ESTM principle is especially suitable for polar compounds and metals, in contrast to SPME-based methods [65], which are more suitable for nonpolar compounds. ESTM has been evaluated both with phenolic pollutants [32] and metal ions [66,67]. An analogous problem in pharmacology is the measurement of drug-protein binding, to which ESTM has been successfully applied [33,68].

## 12.4 APPARATUS FOR MEMBRANE EXTRACTION

### 12.4.1 STAND-ALONE EQUIPMENT

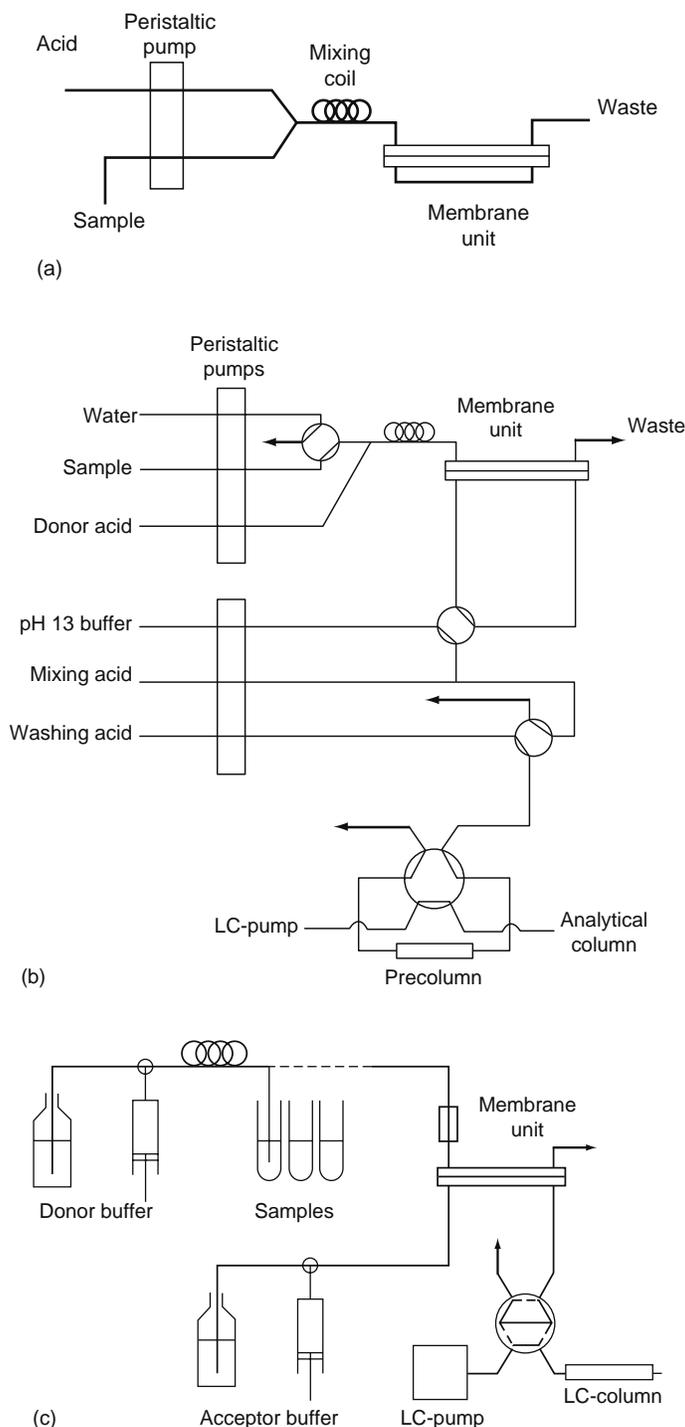

Simple and cheap membrane extraction flow systems for relatively large sample volumes can be built up around a peristaltic pump. An example of such a system is seen in Figure 12.6a. Here, the sample is pumped through the donor channel and the acceptor phase is manually removed by the use of a syringe after each extraction. Such systems have been used both for laboratory work [69,70] and for sampling in natural waters [71]. An tutorial for the operation of this type of devices has been published [8].

Hollow fiber devices working in flow systems are also known [34]. In those cases, either single fibers or bundles of fibers, perhaps in commercial cartridges, are employed and used in flow system configurations.

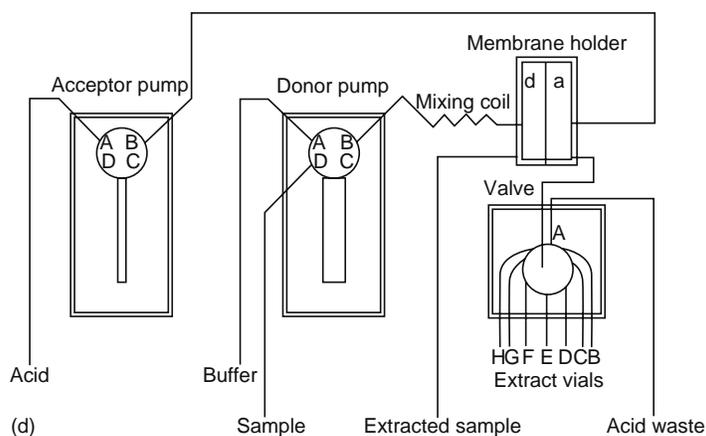

### 12.4.2 ONLINE CONNECTION TO CHROMATOGRAPHY

For online connection to HPLC, SLM is the preferred extraction technique, as the extract obtained is aqueous and therefore in principle compatible with HPLC. With large membrane units (channel volumes around 1 mL), direct transfer of the entire volume

of the acceptor phase to an HPLC can be arranged by a precolumn [72,73] to inject as much as possible of the extracted analyte. See Figure 12.6b. Such systems can be automated with pneumatically or electrically actuated valves controlled by timers or by computer systems. Smaller membrane channels can also be used. Then a heart-cut, which contains a major part of the extract, can be accommodated in the injection loop for direct injection into the HPLC column without a precolumn [41,74,75].

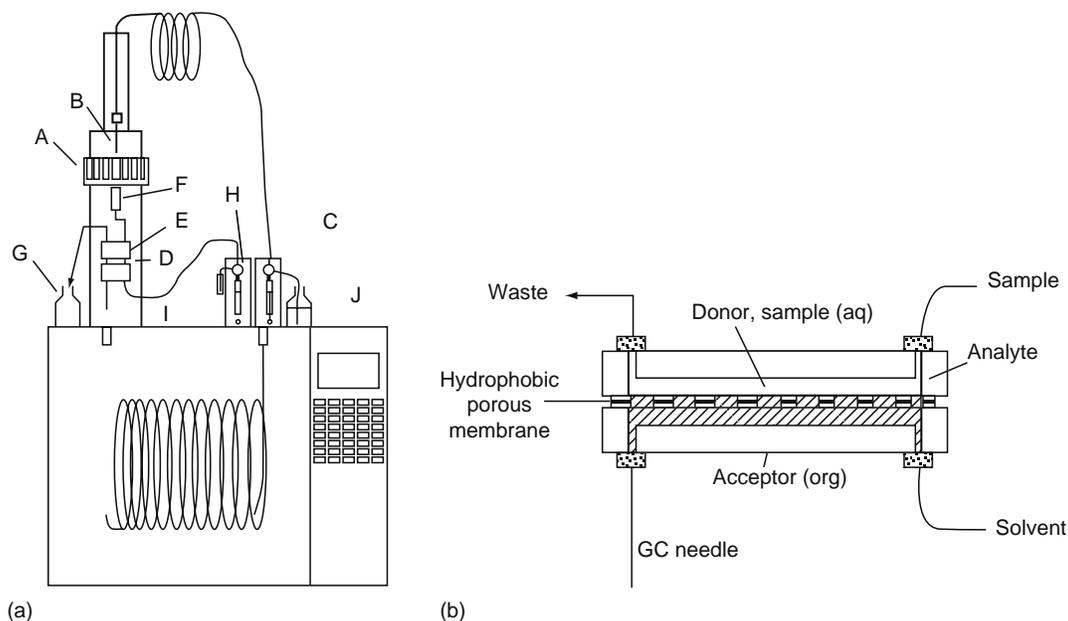

**FIGURE 12.6** Technical setups for membrane extraction. (a) Manual system, utilizing a peristaltic pump. (From Knutsson, M., Nilvé, G., Mathiasson, L., and Jönsson, J.Å., *J. Agric. Food Chem.*, 40, 2413, 1992. With permission.) (b) Automated setup with peristaltic pump and large (1 mL) channel volumes, connected on-line to HPLC. (From Nilvé, G., Knutsson, M., and Jönsson, J.Å., *J. Chromatogr. A*, 668, 75, 1994. With permission.) (c) Automated setup with syringe pumps and small (10  $\mu$ L) channel volumes connected on-line to HPLC. (From Lindegård, B., Björk, H., Jönsson, J.Å., Mathiasson, L., and Olsson, A.-M., *Anal. Chem.*, 66, 4490, 1994. With permission.)

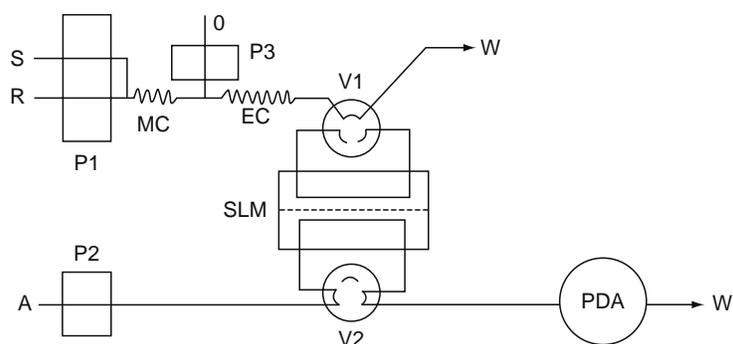

**FIGURE 12.6 (continued)** (d) Portable field sampler, based on syringe pumps. (From Larsson, N., Jönsson, J.Å., Megersa, N., and Berhanu, T., Portable and time integrating field sampling for continuous membrane extraction of *s*-triazine pesticides and their metabolites in a lake in agricultural region of Southern Ethiopia. Manuscript in preparation.)

For small samples (<1 mL) and small channel volumes, the liquid delivery precision of peristaltic pumps is not adequate and membrane extraction equipment based on syringe pumps connected to robotic liquid handlers can be applied [25,64]. A typical example is shown in Figure 12.6c. Here, a robotic needle connected to a syringe pump submits reagent to adjust the pH of samples in the vials, picks up an aliquot and passes it through the donor channel of a small membrane unit (channel volume around 10  $\mu\text{L}$ ). The entire extract collected in the acceptor channel is then transferred to an injection loop injector connected to the HPLC system in the usual manner. Thus, the entire extract from for example 1 mL sample ends up in one chromatographic injection. Typically, while one sample is chromatographed, the next sample is extracted, so the cycle time of the system is determined by the chromatogram time.

For gas chromatography, the most suitable membrane extraction technique is MMLLE. The organic acceptor is better compatible with GC than with HPLC, as are the analytes that are best extracted in such a system, i.e., relatively hydrophobic compounds. A new development is the ESy instrument (ESyTech AB, Lund, Sweden) [76–78] where an MMLLE extraction in microscale (1 mL extracted into a volume ca 1  $\mu\text{L}$ ) is automatically performed and the organic extract is directly injected into the GC by an injection needle, directly connected to the extraction cell. See Figure 12.7.

**FIGURE 12.7** Experimental setup for the ESy system. (From Barri, T., Bergström, S., Norberg, J., and Jönsson, J.Å., *Anal. Chem.*, 76, 1928, 2004. With permission.) (a) General setup (A, sample tray; B pipette; C, sample pump; D, membrane; E, extraction card; F, pipette port; G, waste; H, solvent pump; I, needle; J, washing solution) and (b) ESy extraction card with 1.65  $\mu\text{L}$  acceptor and donor channels.

**FIGURE 12.8** Schematic diagram of the CFLME system. (From Liu, J.-F., Chao, J.-B., and Jiang, G.-B., *Anal. Chim. Acta*, 455, 93, 2002. With permission.) ### 12.4.3 CONTINUOUS FLOW LIQUID MEMBRANE EXTRACTION

By combining continuous flow LLE and SLM extraction, a novel aqueous–aqueous extraction technique termed continuous flow liquid membrane extraction (CFLME) was developed for trace-enrichment [79]. The setup is shown in Figure 12.8. The aqueous sample is mixed with an organic solvent in a flow system, and the analyte is extracted into the organic phase. This is then transported to the liquid membrane formed in the microporous membrane of the SLM equipment. Finally, it is transferred through the liquid membrane and is trapped by the acceptor. Chemically, this is a three-phase extraction system, analogous to SLM, but it overcomes a disadvantage of SLM, as it is possible to use also relatively volatile and also polar solvents with this principle. On the other hand, it involves a more technically complex arrangement, and it typically requires more solvent (although still very little) than SLM.

### 12.4.4 MEMBRANE EXTRACTION WITH A SORBENT INTERFACE

The techniques mentioned above are all characterized by liquid donor and acceptor phases. However, a gaseous acceptor phase is also possible, and that would be the most convenient and compatible arrangement for direct connection with gas chromatography. This is realized with the membrane extraction with a sorbent interface (MESI) technique [80–82]. MESI can be used for either gaseous or aqueous samples and the equipment employs a membrane module with a (usually) silicone rubber hollow fiber, into which the analytes are extracted from the surrounding liquid or gaseous sample. The carrier gas of a gas chromatograph flows inside the fiber and transports the analyte molecules as they are extracted from the membrane into a cooled sorbent trap where they are trapped. The analytes are subsequently desorbed from the sorbent trap by heating and are transferred to GC analysis.

In Figure 12.9, a typical MESI setup is shown. Sampling can also be made off-line with the extraction module and sorbent trap in, for example, field sampling and the sorbent trap can later be connected to the GC and desorbed in a separate step. Matz [83] recently presented and compared this and a few other variants.

**FIGURE 12.9** Schematic of the MESI system. (From Segal, A., Górecki, T., Mussche, P., Lips, J., and Pawliszyn, J., *J. Chromatogr. A*, 873, 13, 2000. With permission.)

### 12.4.5 FIELD SAMPLING APPARATUS

Simple flow systems comprising flat membrane devices and a peristaltic pump were used for field sampling in natural waters [71] and also for sampling of nutrient solutions for soil-free (hydroponics) growing in greenhouses [70].

A portable sampler (Figure 12.6d) based on syringe pumps and powered by batteries and solar power was recently constructed and used for sampling of triazine herbicides in Ethiopian lakes [84].

## 12.5 APPLICATIONS

Over the last decade, a large number of applications to membrane extraction have been presented. In Tables 12.3 through 12.5, incomplete listings of such applications are presented, divided into environmental, biomedical, and other (mainly industrial) applications. The wide variety of analytes and sample types shows that membrane extraction is very versatile and is an useful tool for the analytical chemist.

**TABLE 12.3**  
**Environmental Applications of Membrane Extraction**

Analytes	Matrices	Membrane Technique	Analytical Technique	References
Metals	Water	SLM	AAS, electrochem	[50,51,55,66,96–106] [101]
Metals	Water	SLM (ESTM)	AAS, Spek	[66,67]
Phenoxy acids	Water	SLM	HPLC	[71,107]
Sulfonylurea herbicides	Water	SLM	HPLC	[73]
Phenolics	Water, nutrient solutions	SLM; LPME3	HPLC	[69,70,72] [108]
Phenolics	Water	LPME3 (ESTM)	HPLC	[32]
Carboxylic acids	Soil liquid, Air	SLM	IC	[74,109,110]
Anilines	Water	SLM	HPLC	[111]
Anionic surfactants	Water	SLM	HPLC	[59]
Glyphosate	Water	SLM	CE	[90,112]
Triazine herbicides	Water	SLM	HPLC	[63,113–116] [117]
Herbicides	Water	SLM	HPLC	[118]
Aliphatic amines	Air (impinger samples)	SLM (gas)	GC	[119,120]
Carboxylic acids	Air (impinger samples)	SLM	IC	[121]
Fungicides	Water	SLM, MMLLE	HPLC	[122,123]
PAH	Soil	MMLLE	GC	[124,125]
PCB	Water	MMLLE (ESy)	GC	[77]
Amines	Water	MMLLE	CE	[126]
Nonylphenol, etc.	Water	MMLLE	HPLC	[127]
Triazine herbicides	Water	MMLLE	FIA	[128]
Cationic surfactants	Water	MMLLE	HPLC	[129]
Semi-volatile organics	Water	PME	HPLC	[130–132] [42]
Organics	Water	PME (MASE)	GC/MS	[44,133–135]
Volatile organics	Water, air	MESI	GC	[82,136–140]
Phenols, sulfonylureas	Water	CFLME	HPLC, CE	[141–146]
Amines	Water	LPME3	HPLC	[147]
Drugs	Water	LPME3	CE, LC/MS	[148–150]
Phenoxy acid herbicides	Milk	LPME3	HPLC	[151]
Triazine herbicides	Water	LPME2	GC/MS	[152]
Phthalate esters	Water	LPME2	GC/MS	[153]
Pesticides	Water	LPME2	GC/MS	[154–156]
Drugs	Water	LPME2	GC/MS	[157]
Vinclozoline	Water, soil	LPME2	GC	[158]
PAH	Soil	LPME2	GC	[159]
Explosives	Water	LPME2	GC	[160]

*Note:* SLM, supported liquid membrane (aq/org/aq); MMLLE, microporous membrane liquid–liquid extraction (aq/org); PME, polymer membrane extraction (aq/polymer/org); MESI, membrane extraction with sorbent interface (aq (or gas)/polymer/gas/sorbent); CFLME, continuous flow liquid membrane extraction (aq/org (in flow)/aq); LPME2, two-phase liquid phase microextraction in hollow fibers (aq/org); LPME3, three-phase liquid phase microextraction in hollow fibers (aq/org/aq).

**TABLE 12.4**  
**Applications of Membrane Extraction to Biological Samples**

Analytes	Matrices	Membrane Technique	Analytical Technique	References
Aliphatic amines	Urine	SLM	GC	[161]
Aliphatic acids	Manure	SLM	GC	[162]
Aliphatic amines	Blood plasma	SLM	GC	[163]
Amperozide	Blood plasma	SLM	HPLC	[25]
Bambuterol	Blood plasma	SLM	CE	[164–166]
Bambuterol	Blood plasma	SLM	LC-CE	[167]
Diprivan (Propofol)	Urine	SLM	HPLC	[168]
Phenols	Blood plasma	SLM	HPLC-biosensor	[169]
Peptides	Blood plasma	SLM	HPLC	[54]
Drugs	Blood plasma	SLM (ESTM) LPME3 (ESTM)	HPLC	[33,68]
Lead	Urine	SLM	AAS	[56]
Lead	Urine	SLM	PSA	[170]
Local anesthetics	Blood plasma	SLM	GC	[86]
Local anesthetics	Blood plasma	MMLLE	GC	[171]
Amphetamine	Blood plasma, urine	LPME3 (LLLME)	CE	[26]
Amphetamines, benzodiazepines, naproxen, citalopram	Blood plasma, urine	LPME2, LPME3	HPLC, GC, CE	[172]
Benzodiazepines	Blood plasma, urine	LPME2	GC	[173]
Ibuprofen, naproxen, ketoprofen	Urine	LPME3	CE	[174]
Metabolites of Ropivacaine	Urine	SLM	HPLC	[64]
Citalopram and metabolites	Blood plasma	LPME3	CE	[175]
Amphetamines	Blood, urine	LPME3	FIA-MS/MS	[27]
Organophosphate esters	Blood plasma	MMLLE	GC-MS	[176]
Sulfonylurea drugs	Blood plasma	PME (off-line)	LC-MS/MS	[177]
Amphetamine	Urine	SLM	HPLC	[178]
Benimidazole anthelmintics	Urine, tissue, milk	SLM	HPLC, LC-MS	[179]

*Note:* Abbreviations as in Table 12.3.

Phenols	Gasoline, kerosene	PME	HPLC	[183]
Phenols	Crude oil, fuels	PME	HPLC	[184]
Vitamin E	Butter	PME	HPLC	[75]
Nicotine	Snuff	SLM (solid sample)	UV	[185]
Caffeine	Coffee, tea	SLM (solid sample)	UV	[186]
Pesticides	Eggs	PME	HPLC	[187]
Vanillin	Various food	SLM (solid sample)	Amperometric	[188]
Anionic surfactants	Detergents	MMLLE	FIA	[189]
Phenols	Pyrolysis oil	MMLLE	LC-LC	[190]
Biogenic amines	Wine	SLM	HPLC	[58]

*Note:* Abbreviations as in Table 12.3.

## ACKNOWLEDGMENTS

During recent years, the membrane extraction work at Lund University was supported by grants from the Swedish Science Research Council (VR), the Foundation for Strategic Environmental Research (Mistra), the Swedish Institute (SI), the Swedish International Development Co-operation Agency (SIDA), the Crafoord Foundation, and the Wenner-Gren Foundation. The work would not have been possible without a number of colleagues, especially Professor Lennart Mathiasson, several graduate and undergraduate students, as well as postdoctoral fellows and other guest researchers.

## 13.1 INTRODUCTION AND DEFINITIONS

Permeation is a general term for the concentration-driven membrane-based mass transport process. Application of a pressure difference, an electric field, or temperature considerably intensifies the process, but these special methods are beyond the scope of this overview. Three groups of liquid membranes are usually considered: bulk liquid membrane (BLM), supported liquid

**FIGURE 13.1** Schematic transport models of an OHLM system with a, c: hydrophobic membranes; b, d: hydrophilic or ion-exchange membranes. (From Kislik, V. and Eyal, A., *J. Mem. Sci.*, 111, 273, 1996. With permission.)

membrane (SLM), or immobilized liquid membrane (ILM), and emulsion liquid membrane (ELM). The scope of this chapter is BLM processes.

The term organic hybrid liquid membrane (OHLM) includes all BLM processes incorporating liquid–liquid extraction (LLX) and membrane separation in one continuously working module. OHLM utilizes an extracting reagent (carrier) solution, immiscible with water, circulating or flowing between membranes as barriers. The concept of the OHLM transport is quite simple: a solution of an extracting reagent (carrier phase, E), flows between two membranes, which separate the carrier phase from the feed (F) and receiving (R) phases (see Figure 13.1). A specific solute or solutes diffuse to the F/E interface is extracted from feed phase by an LM extracting reagent as a result of the thermodynamic conditions at the F/E interface, the solute–carrier complex diffuses to the E/R interface and is simultaneously stripped by the receiving phase due to the different thermodynamic conditions at the E/R interface. The membranes are permeable to solutes, but block transfer of the carrier solution to the feed or to the strip solutions. Blocking the carrier is accomplished through membrane hydrophilic/hydrophobic or ion-exchange properties, or through their pore size.

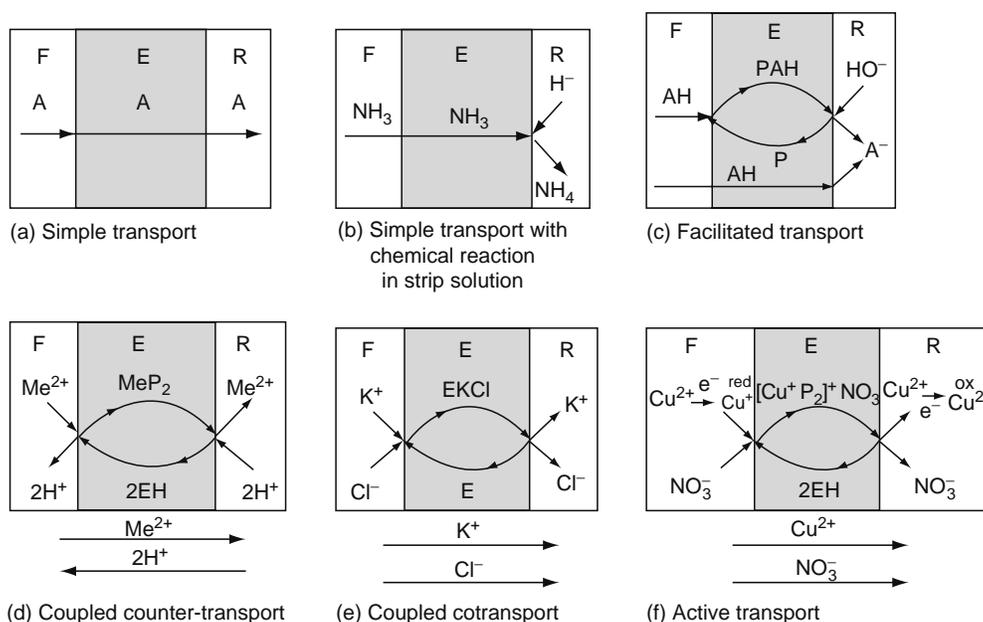

The OHLM term includes several similar LM systems, developed by different research groups, such as hybrid liquid membrane (HLM) by Kislik et al. [1–3], hollow-fiber liquid membrane (HFLM) by Sirkar et al. (HFCLM) [4–8], Schlosser et al. (HFLM) [9–11], pertraction by Boyadzhiev et al. [12–22], Schlosser et al. [23–26], Wodzki et al. [27–29], flowing liquid membranes (FLM) by Teramoto et al. [30–37], membrane-based extraction and stripping by Schlosser et al. [38–40], Kedem et al. [41–43], Eyal et al. [44,45], multimembrane hybrid system (MHS) by Wodzki et al. [46–51]. All these systems are based on the membrane-based nondispersive (as the means for blocking the organic reagent from mixing with the aqueous feed and strip solutions) selective LLX coupled to permselective diffusion of solute–extractant complexes and selective stripping of the solute in one continuous dynamic process. A great number of terms for similar BLM processes confuse the readers. Some of these terms vary by membrane type used (hollow-fiber, flat neutral, ion-exchange sheets) [4–14]; some are by module design [4–8,12–14,23–25,38–40,46–50]. The term pertraction, or perstraction [52] spread over the supported liquid membrane (SLM) and emulsion liquid membrane (ELM) [20,53], what is not so correct, because the SLM (or ILM) and ELM are steady-state processes. Therefore, all above-mentioned BLM processes may be unified under the term OHLM systems.

In this chapter, the basic principles of the OHLM such as interaction mechanisms and theories of transport, design considerations will be analyzed by comparison of modifications of different research groups. Application in the last decade of different modifications of the OHLM systems in solutes separation is presented.

Recently developed aqueous hybrid liquid membrane (AHLM) separation process is similar to the OHLM except the liquid membrane phase is an aqueous solution as are the feed and strip solutions [70,119]. But these systems are not included in this chapter.

### 13.2 THEORY: MASS TRANSFER MECHANISMS AND KINETICS

General properties of liquid membrane systems have been a subject of extensive theoretical studies. Six basic mechanisms of transport are schematically shown in Figure 13.2. In a simple transport (Figure 13.2a), solute passes through due to its solubility

**FIGURE 13.2** Schematic mechanisms of solute transport through the BLMs. A, Me, K, Cu,  $\text{NH}_3$ —solutes, E—carrier, F—feed solution, R—stripping solution. (From Schlosser, S. Pertraction through liquid and polymeric membranes. In: Belafi-Bako, K., Gubicza, L., and Mulder, M. Eds. *Integration of Membrane Processes into Bioconversions*. Proceedings of the 16th European Membrane Society Annual Summer School. Veszprem, Hungary, August 1999. Kluwer Academic/Plenum Publishers, New York, 2000, 73–100. With permission.)

in LM. Permeation stops when concentration equilibrium is reached. The solute is in the same form R in the feed (F), LM (E), and strip (receiving, R) phases. As an example, some carboxylic and amino acids [54,55], phenol transport through xylene, decanol LM [8] may be presented. Uphill transport and selectivity can be achieved at reaction of the solute with components of the stripping solution (see Figure 13.2b).

Facilitated transport takes place when a carrier reacts with a solute on a feed side-LM interface to form complex. This complex reverse reacts on the LM-strip side interface releasing the solute to the strip phase (see Figure 13.2c). Facilitated transport accelerates the transport. For example, trialkylphosphine sulfide increases the rate of phenol transport [11]. At the same time, the simple transport can also take place.

As examples of coupled counter-transport (see Figure 13.2d) and coupled cotransport (see Figure 13.2e) the transport of titanium(IV) from low acidity ( $\text{pH} = 1$ ) and high acidity ( $[\text{H}^+] = 7 \text{ M}$ ) feed solutions, respectively using the HLM system [1,2] may be presented. The di-(2-ethylhexyl) phosphoric acid (DEHPA) carrier reacts with Ti(IV) ion to form complexes on the feed side (see Equations 13.25 and 13.26) and reversible reactions take place on the strip side (see Equations 13.27 and 13.28). Energy for the titanium uphill transport is gained from the coupled transport of protons in the direction opposite to titanium transport from the strip to the feed solutions. In the second case (high-feed acidity), Cl anion cotransported with Ti(IV) cation in the same direction. In both cases fluxes of titanium, protons, and chlorine anion are stoichiometrically coupled.

Active transport (see Figure 13.2f) is driven by oxidation–reduction reactions on the membrane interfaces. No other species are transported in this type of transport. As examples, copper transport by thioether [56] and picrate anions by ferrocene [57,58] as carriers may be presented.

Any universal model for all these types of transport does not exist, and the available knowledge concerning the specific interfacial processes should be taken into account in the description of a real membrane process. There are two general approaches to modeling liquid membrane transport mechanisms: the differential and the integral approach. According to the differential approach [16–22,33–37,59], all phenomena taking place in the feed or in the strip phase, such as diffusion, chemical reactions, etc., are totally ignored. The measured transfer fluxes are dependent on phenomena occurring in the BLM or at the surface of the membrane only. The integral approach [1–12,23–29,40,46–60] considers the three liquid phase system to be a closed\* multiphase system and, therefore, takes into consideration the processes and changes in all three liquids. Most models are very sophisticated because they assume many possible types of control, nonlinear equilibria, phase interactions, etc. The integral approach has been formulated in Ref. [4]:

\* “A closed system is one with boundaries across it, through which no matter may pass, either in or out, but one in which other changes may occur, including expansion, contraction, internal diffusion, chemical reaction, heating, and cooling. An open system is one which undergoes all the changes allowed for a closed system and in addition it can lose and gain matter across its boundaries” [78].

1. Overall mass transfer rate can be controlled by any of the diffusion resistances in the three liquid phases.
2. Aqueous and organic film resistances may be combined with membrane pore diffusion resistance in one-dimensional series of diffusion resistances.

However, the assumption of the steady-state mass transfer through the bulk membrane phase, has been made by some authors [43,61], is oversimplified in many cases, and the assumption of equality of solute distribution coefficients of extraction and back extraction [18,46], is incorrect for most separation systems.

A number of reviews and theoretical articles have appeared on related subjects. Theoretical aspects of the HFLM selective separation processes have been covered in the reviews and articles by Sirkar et al. [4–7,62,63], and in new modifications by Schlosser et al. [9–11,25]. Theory for separations by the FLM is presented in the articles by Teramoto M et al. [31,34–37]; theoretical considerations for rotating film pertraction systems have been described by Boyadzhiev [18,64–68], and theoretical considerations for the MHSs have been described by Wodzki et al. [27,29,46,47,49,51].

Examples of the model considerations, presented below, can be regarded as simplified examples only. The processes have been studied using analytical [1] and numerical [27] solutions for both the local steady-state [1,2,69,70] and dynamic nonstationary [27,71,72] conditions, respectively. Both models, HLM [1] and MHS [27], with some modifications may be used for theoretical analysis of all OHLM systems. Considerations for hollow-fiber systems are presented also in a short.

### 13.2.1 MODEL FOR THE HLM SYSTEM [1–3]

#### 13.2.1.1 Mass Transfer Mechanisms and Kinetics

The theory for HLM was developed for flat thin uncharged symmetric membranes without variation in porosity and pore sizes across the membrane thickness.

To develop three-phase, HLM system model [1,2], the transport model simplification analysis, developed by Shagxu Hu [73] for the two-phase system, is used.

Titanium, as an example for the transport model verification, was chosen because of the extensive experimental data available on LLX and membrane separation [1,2,74–76] and of its extraction double-maximum acidity dependence phenomenon [74]. This behavior was observed for most extractant families: basic (anion exchangers), neutral (complexants), and acidic (cation exchangers). So, it is possible to study both counter- and cotransport mechanisms at  $\text{pH} \geq 0.5$  and  $[\text{H}]^+ \geq 7 \text{ mol/kg}$  feed solution acidities, respectively, using neutral (hydrophobic, hydrophilic) and ion-exchange membranes.

In general, the mass transfer rate (or flux) of any solute passing through the barrier (membrane) is a function of distance and time:  $J = f(x, t)$ . First, let us consider the flux as a function of distance.

Three liquids, having bulk solute *i* concentration  $[C_i]_F$ ,  $[C_i]_E$ , and  $[C_i]_R$ , constant volumes  $V_F$ ,  $V_E$ , and  $V_R$ , respectively, are separated by two membranes with the same working area *S*. Stirring of bulk liquids is effective in such a way that the aqueous ( $h_{fe}$ ,  $h_{re}$ ) and the organic ( $h_{ef}$ ,  $h_{er}$ ) boundary layers become sufficiently thin and constant. Concentration profiles in the HLM system with hydrophobic membranes are demonstrated in Figure 13.3, while those containing hydrophilic or ion-exchange membranes are demonstrated in Figure 13.4.

Using the concept of the one-dimensional series of diffusion resistances, and regarding the principle of resistance additivity [1–40,46–53], the overall mass transfer coefficients or permeability coefficients [58,77]  $K_F$  on the feed side and  $K_R$  on the strip side are related to the individual films (including membrane barrier) mass transfer coefficients, *k*:

For hydrophobic membranes, for hydrophilic or ion-exchange membranes

For hydrophobic membranes

$$K_F = \frac{k_{fe}k_{mf}k_{ef}E_F}{k_{fe}k_{ef} + k_{fe}k_{mf} + k_{mf}k_{ef}E_F} \quad (13.1a)$$

$$K_R = \frac{k_{re}k_{mr}k_{er}}{k_{mr}k_{er}E_R + k_{mr}k_{re} + k_{re}k_{er}} \quad (13.2a)$$

For hydrophilic or ion-exchange membranes

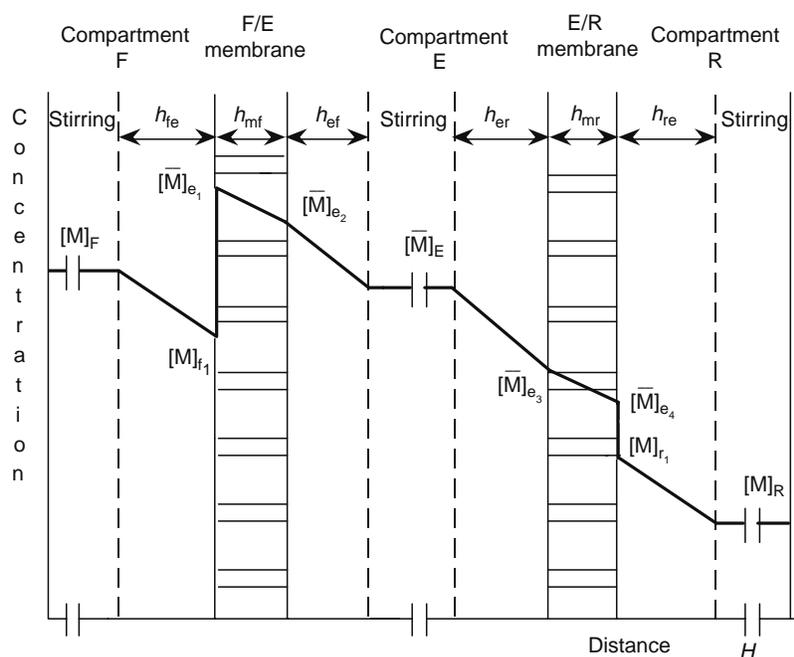

$$K_F = \frac{k_{fe}k_{mf}k_{ef}E_F}{k_{fe}k_{mf} + k_{fe}k_{ef}E_F + k_{mf}k_{ef}E_F} \quad (13.1b)$$

$$K_R = \frac{k_{re}k_{mr}k_{er}}{k_{mr}k_{er}E_R + k_{re}k_{er}E_R + k_{mr}k_{re}} \quad (13.2b)$$

where  $E_F$  and  $E_R$  are distribution coefficients of solutes between membrane and aqueous feed, and strip phases, respectively at local equilibrium.

Individual film mass transfer coefficients may be determined by the following considerations. According to postulates of nonequilibrium thermodynamics [78], the general equation that relates the flux, *J*, of the solute to its concentration, *C*, and its derivative, is [79]

$$J = UC - D \frac{dC}{dx} \quad (13.3)$$

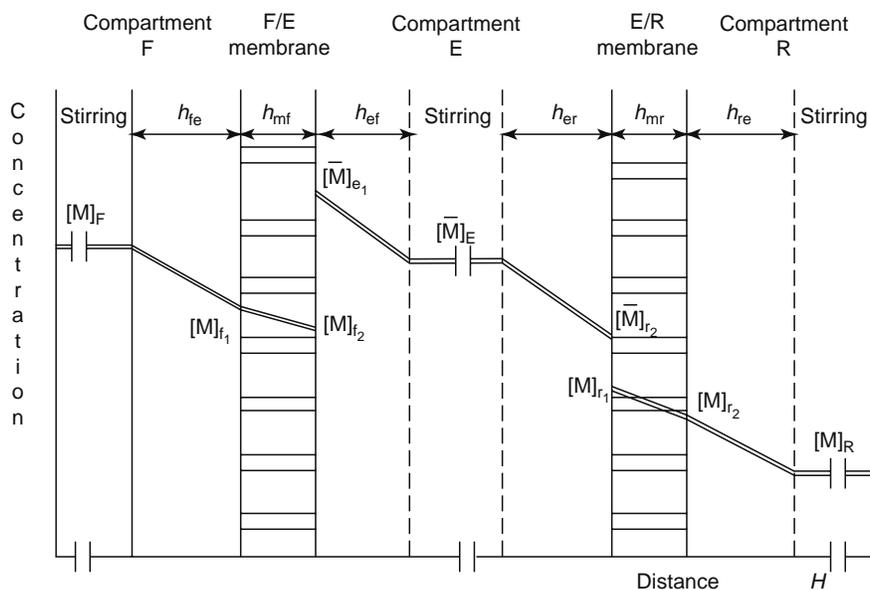

**FIGURE 13.3** Schematic concentration profile of each Ti(IV) chemical species, transported through the HLM system with hydrophobic membranes. Layers controlling the permeation rate are  $h_{fe}$ , feed-side aqueous boundary layer;  $h_{mf}$ , feed-side microporous membrane, immobilized by membrane solution;  $h_{ef}$ , feed-side boundary layer of the membrane solution;  $h_{er}$ , strip-side boundary layer of the membrane solution;  $h_{mr}$ , strip-side microporous membrane, immobilized by membrane solution;  $h_{re}$ , strip-side aqueous boundary layer. (From Kislik, V. and Eyal, A., *J. Mem. Sci.*, 111, 259, 1996. With permission.)

where

$U$  is the flow rate

$D$  is the sum [80] of all effective diffusion coefficients

**FIGURE 13.4** Schematic concentration profile of each Ti(IV) chemical species, transported through the OHLM with hydrophilic or ion-exchange membranes. Layers controlling the permeation rate are the same as those in Figure 13.3, except for  $h_{mf}$ , feed-side microporous membrane is immobilized by feed aqueous solution;  $h_{mr}$ , strip-side microporous membrane is immobilized by strip aqueous solution. (From Kislik, V. and Eyal, A., *J. Mem. Sci.*, 111, 259, 1996. With permission.)

Referring to the equation of continuity, as  $x$  approaches zero, the steady-state zones or layers are formed next to the phase's interface (but not for the bulk phases, where  $x \gg 0$ ). Separation then occurs by differential displacement permeation through the interface. Efficiency of the separation hinges directly on the distribution of solute in the steady-state layers.

Using Giddings' analysis [81] of such a system we obtain

$$\ln \left[ \left( C - \frac{J_o}{U} \right) / \left( C_o - \frac{J_o}{U} \right) \right] = U \frac{h}{D} \quad (13.4)$$

According to [4-40,46-53,67,72,82,83] the mass transfer coefficient of every layer,  $k_i$ , is

$$k_i = \frac{D_i}{h_i} \quad (13.5)$$

where

$D_i$  is the free diffusion coefficient of the solute in the layer

$h_i$  is the thickness of the layer [72]

Replacing Equations 13.4 with 13.5 we obtain

$$k_i = U \left\{ \ln \left[ \left( C_i - \frac{J_{ss}}{U} \right) / \left( C_{i-1} - \frac{J_{ss}}{U} \right) \right] \right\}^{-1} \quad (13.6)$$

where

$C_i$  is the concentration of the solute in the bulk solution at time of sampling  $t_i$

$C_{i-1}$  is the concentration of the solute in the same solution at time of previous sampling  $t_{i-1}$

According to Sirkar's assumption [84], diffusion mass transfer rate through a membrane having a solvent-filled pore (hydrophobic), or an aqueous solution-filled pore (hydrophilic or ion exchange) may be expressed through the diffusion coefficients of the solute in the respective interface layers:

For hydrophobic membranes

$$k_{mf} = \frac{D_{ef} \varepsilon_m}{h_{mf} \tau_m} \quad (13.7a)$$

$$k_{mr} = \frac{D_{er} \varepsilon_m}{h_{mr} \tau_m} \quad (13.8a)$$

For hydrophilic or ion-exchange membranes

$$k_{mf} = \frac{D_{fe} \varepsilon_m}{h_{mf} \tau_m} \quad (13.7b)$$

$$k_{mr} = \frac{D_{re} \varepsilon_m}{h_{mr} \tau_m} \quad (13.8b)$$

where

$\varepsilon_m$  is the membrane porosity

$\tau_m$  is the membrane tortuosity

These expressions are valid when the following assumptions are held:

- There is unhindered diffusion of the solute (solute dimensions  $10^2 \leq$  pore dimensions).
- Membrane is symmetric and completely wetted by the designated phase.
- No two-dimensional effects occur.

Applicability of these expressions for charged membranes is doubtful because of hindered diffusion of solute in their pores, but it may be evaluated experimentally. One more serious simplification is that the influence of the flow velocities extends inside the membrane pores.

Another way of evaluating mass transfer coefficients through the membranes may be proposed, providing the membranes possess the same properties (diffusion resistance, porosity, tortuosity, etc.). They may, however, be of different thicknesses. It is clear from Equation 13.4 that diffusion coefficient (exactly  $U/D$ , where  $U$  is known) of the solute through the feed-side and strip-side membranes may be evaluated as a slope of the plots:

$$-\ln\left(\frac{C}{C_0}\right)F = f(h_{mf}) \quad (13.9)$$

$$\ln\left(\frac{C}{C_0}\right)R = f(h_{mr}) \quad (13.10)$$

Individual mass transfer coefficients of the solute (for example, titanium compound) can be experimentally determined in every layer and membrane. Thus, overall mass transfer coefficients of the feed ( $K_{cF}$ ) and strip ( $K_{cR}$ ) sides of the OHLM system may be calculated from Equations 13.1a, 13.1b, 13.2a, and 13.2b.

Now the concentration profiles in the system, as a function of time, can be analyzing.

Introducing the assumptions as

- Linear concentration gradients
- Concentration of the solute permeating species is lower than that of the carrier in the membrane phase
- Instantaneous interfacial chemical reactions and local reaction equilibria at the interfaces [1,4–8,30–37,46–51, 61,77,84]

we can derive the transport rate and distribution relation equations for any solute  $[M]$  permeating species:

$$V_F \left( \frac{d[M]_F}{dt} \right) = -SK_F([M]_F V_F - [\bar{M}]_E V_E) \quad (13.11)$$

$$V_E \left( \frac{d[\bar{M}]_E}{dt} \right) = SK_F([M]_F V_F - [\bar{M}]_E V_E) - SK_R([\bar{M}]_E V_E - [M]_R V_R) \quad (13.12)$$

From overall material balance of the system

$$[M]_R = \frac{Q^0}{V_R} - \frac{V_F}{V_R} [M]_F - \frac{V_E}{V_R} [\bar{M}]_E \quad (13.13)$$

where

$[M]_F^0$ ,  $[\bar{M}]_E^0$ , and  $[M]_R^0$  are initial concentrations of a solute specie in the feed, membrane, and strip phases, respectively  
 $Q^0$  is the overall initial quantity of the solute in the OHLM system

The system described in Equations 13.11 through 13.13 results in an analytical solution under the assumption that the mass transfer coefficients are constant\* (at flow or stirring rates constant). Following are complete set of the model equations:

$$[M]_F = \frac{\gamma}{\beta} + C_1 e^{\gamma t} + C_2 e^{\alpha t} \quad (13.14)$$

$$[\bar{M}]_E = \left[ \frac{\gamma}{\beta} + C_1 e^{\gamma t} \left( 1 + \frac{\gamma_1}{k_F S} \right) + C_2 e^{\alpha t} \left( 1 + \frac{\gamma_2}{k_F S} \right) \right] \frac{V_F}{V_E} \quad (13.15)$$

$$[M]_R = \frac{Q^0}{V_R} - [M]_F \frac{V_F}{V_R} - [\bar{M}]_E \frac{V_E}{V_R} \quad (13.16)$$

$$\alpha = 2S(K_F + K_R) \quad (13.17)$$

$$\beta = 3S^2 K_F K_R \quad (13.18)$$

$$\gamma = K_F K_R \frac{S^2}{V_F} Q^0 \quad (13.19)$$

$$\frac{\gamma}{\beta} = \frac{Q^0}{3V_F} = \frac{[M]_F^0 V_F + [\bar{M}]_E^0 V_E + [M]_R^0 V_R}{3V_F} \quad (13.20)$$

\* In the real continuous OHLM system, mass transfer coefficients  $K_F$  and  $K_R$  may be close to constant at the stabilized conditions of the process (acidity or pH, temperature, flow rates, etc.).

$$y_1 = -\frac{\alpha}{2} + \sqrt{\frac{\alpha^2}{4} - \beta} \quad (13.21)$$

$$y_2 = -\frac{\alpha}{2} - \sqrt{\frac{\alpha^2}{4} - \beta} \quad (13.22)$$

$$C_1 = \frac{y_2 \left( [M]_F^0 - \frac{\gamma}{\beta} \right) - SK_F \left( [\overline{M}]_E^0 \frac{V_E}{V_F} - [M]_F^0 \right)}{y_2 - y_1} \quad (13.23)$$

$$C_2 = -\frac{y_1 \left( [M]_F^0 - \frac{\gamma}{\beta} \right) - SK_F \left( [\overline{M}]_E^0 \frac{V_E}{V_F} - [M]_F^0 \right)}{y_2 - y_1} \quad (13.24)$$

### 13.2.1.2 Driving Forces

The transport of titanium(IV) species through HLM can be formally described as a simultaneous combination of diffusion, extraction, and stripping operations occurring in nonequilibrium conditions. These systems are very complicated to analyze and therefore, some assumptions are needed for simplification. Extraction kinetics and stripping processes are much faster for most metal ions than their diffusion, and many researchers have adopted the local extraction equilibrium of feed-extractant and extractant-strip phases at the membrane interfaces. So, the chemistry of the OHLM system at equilibrium conditions has to be analyzed.

The chemical reactions responsible for the transport can be schematized [74–76].

At the feed solution–membrane (carrier) solution interface, for feed at low acidity (pH region)

at high (>7 mol/kg) acidity

At the membrane solution–strip solution interface, at low acidity (pH region)

at high acidity

These reactions are characterized by equilibrium constants:

$$K_{F/E} = \frac{\overline{[\text{TiL}_4 * 2\text{H}_2\text{O}]_E} * [\text{H}]_F^4}{[\overline{\text{HL}}_E]^4 * [\text{Ti} * 2\text{H}_2\text{O}]_F} = E_F * \left( \frac{[\text{H}]_F}{[\overline{\text{HL}}_E]} \right)^4 \quad (13.29)$$

or

$$K'_{F/E'} = \frac{\overline{[\text{TiL}_4 * 2\text{HCl}]_E} * [\text{H}]_F^4}{[\overline{\text{HL}}_E]^4 * [\text{Ti} * 2\text{HCl}]_F} = E_{F'} * \left( \frac{[\text{H}]_F}{[\overline{\text{HL}}_E]} \right)^4 \quad (13.29a)$$

$$K_{E/R} = \frac{[\text{TiO}]_R * [\overline{\text{HL}}_E]^4 * [\text{H}_2\text{O}]}{\overline{[\text{TiL}_4 * 2\text{H}_2\text{O}]_E} * [\text{H}]_R^2} = \frac{[\overline{\text{HL}}_E]^4}{[\text{H}]_R^2} * E_R \quad (13.30)$$

or

$$K'_{E/R'} = \frac{[\text{TiO}]_R * [\overline{\text{HL}}]_E^4 * [\text{CL}]_R^2}{[\text{TiL}_4 * 2\text{HCl}] * [\text{H}_2\text{O}]} = \frac{[\overline{\text{HL}}]_E^4 * [\text{Cl}]_R^2}{E_R} \quad (13.30a)$$

where  $E_F$  and  $E_R$  are distribution coefficients of titanium ions between membrane and aqueous feed, and strip phases, respectively and concentration of  $\text{H}_2\text{O}$  is neglected.

$$K = K_{F/E} * K_{E/R} = \left(\frac{E_F}{E_R}\right) \left(\frac{[\text{H}]_F^4}{[\text{H}]_R^2}\right) \quad (13.31)$$

or

$$K' = K'_{F/E} * K'_{E/R} = \left(\frac{E'_F}{E'_R}\right) ([\text{H}]_F^4 * [\text{Cl}]_R^2) \quad (13.31a)$$

$K$  (or  $K'$ ) is denoted as a driving force coefficient of the HLM system. Consider

$$K = K_c * K_d \quad \text{where } K_c = \frac{E_F}{E_R} \quad \text{and } K_d = \frac{[\text{H}]_F^4}{[\text{H}]_R^2} \quad (13.32)$$

or

$$K' = K'_c * K'_d \quad \text{where } K'_c = \frac{E'_F}{E'_R} \quad \text{and } K'_d = [\text{H}]_F^4 * [\text{Cl}]_R^2 \quad (13.32a)$$

$K_c$  is denoted as an internal [83] (carrier) driving force coefficient, derived from extraction distribution ratio between liquid membrane phase and feed, and receiving phases.  $K_d$  (or  $K'_d$ ) is denoted as an external driving force coefficient, derived from the coupling effect of the HLM system.

These initial parameters are easily accessible experimentally by equilibrium extraction experiments [75]. For example, extraction of titanium(IV) from 0.1 mol/kg Ti(IV) hydrochloric acid solutions at 0.45 mol/kg (pH = 0.65), 2 mol/kg and at 7 mol/kg HCl by 1 mol/kg DEHPA in benzene, at aqueous phase/organic phase = 5/1, have shown the initial distribution coefficients (for details, refer to [75]):

$$\begin{aligned} E_{F1} &= 20-25 \text{ for the aqueous phase at pH} = 0.65, \\ E_{F2} &= 200-220 \text{ for the aqueous phase at } 7.0 \text{ mol/kg HCl}, \\ E_R &= 1.5-2.0 \text{ for the aqueous phase at } 2.0 \text{ mol/kg HCl}. \end{aligned}$$

The initial distribution ratios  $K_c = E_F/E_R$  (internal or liquid membrane driving force coefficients) are

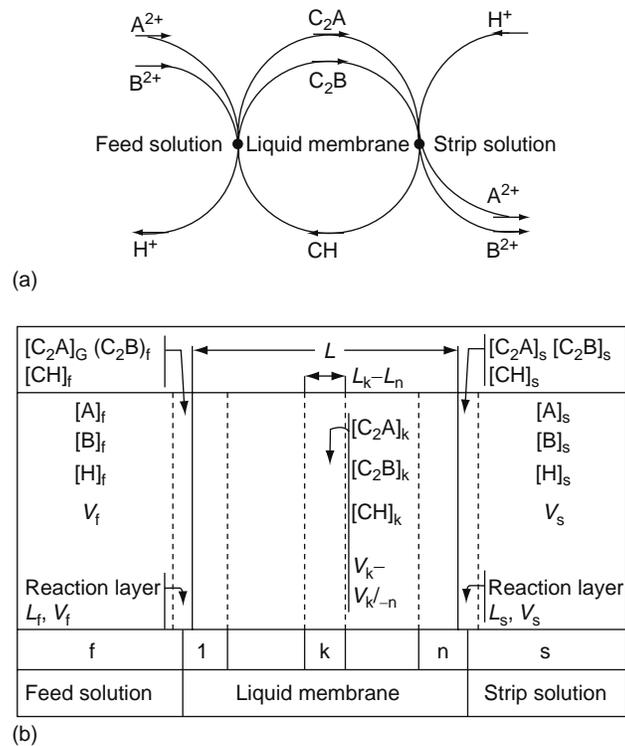

$$K_c = 10-15 \quad K'_c = 100-150$$

Of course, during the transport process in the closed HLM system, the distribution ratio will change in accordance with changing feed and strip phase conditions (acidities, titanium concentration, etc.). At  $K_c = 1$  ( $E_F = E_R$ ), concentration of titanium (IV) in the carrier solution should be  $[\text{Ti}]_R E_R$  (the system at equilibrium). Therefore,  $E_R$  may be denoted as an irreversible coefficient of the HLM for both, closed and open [78] systems (flowing feed, strip streams, buffered acidities, etc.).  $K_c$  is an “uphill pumping” border of the HLM system.

### 13.2.2 NUMERICAL MODEL OF COMPETITIVE $\text{M}^{2+}/\text{H}^+$ COUNTER-TRANSPORT [27,86–89]

A mathematical model to be solved numerically has been developed and used to predict the separation effects caused by nonstationary conditions for a liquid membrane transport. Numerical calculations were made to compute pertraction\* characteristics such as input and output membrane selectivity (ratio of respective fluxes), concentration profiles for cations bound by a carrier in a liquid membrane phase, and the overall separation factors. These quantities are discussed as dependent

\* The term “pertraction,” used by the authors [27,86] has not been changed in the following text (for explanations see Section 13.1).

**FIGURE 13.5** (a) Scheme of  $A^{2+}$ ,  $B^{2+}/H^+$  competitive counter-transport mediated by an ionic carrier CH; (b) Compartmental model of pertraction system. (From Wodzki, R., Szczepanska, G., and Szczepanski, P., *Sep. Purif. Technol.*, 36, 1, 2004. With permission.)

on time, the kinetic constants of interfacial reversible reactions, and diffusion coefficients of carrier species in a liquid membrane phase. The computations of fluxes and separation factors as dependent on time have revealed high separation efficiency of unsteady-state pertraction as compared with steady or near-steady-state process (with reactions near equilibrium state).

The mechanism of competitive pertraction system (CPS) is presented schematically in Figure 13.5 together with the compartmental model necessary for constructing the reaction–diffusion network. The overall pertraction process consists of a set of diffusion steps and reactions leading to the uptake or release of cations at two formally independent and possibly different interfaces. The simple flat-layered BLM of the thickness  $L_m$  and interface area  $S$  separates the two reservoirs (f, feed; and s, stripping) containing transported divalent cations  $A^{2+}$  and  $B^{2+}$  (most frequently  $Zn^{2+}$  and  $Cu^{2+}$  or  $Ca^{2+}$  and  $Mg^{2+}$ ) or antiported univalent cations  $H^+$ . At any time of pertraction  $t$ , their concentrations are  $[A]_f$ ,  $[B]_f$ ,  $[H]_f$ , and  $[A]_s$ ,  $[B]_s$ , and  $[H]_s$ , for the feed and stripping solution, respectively. The hydrophobic liquid membrane contains a carrier (C) of the total concentration  $[C]$ . The carrier is confined to the membrane phase and cannot dissolve at the adjacent aqueous solutions. Its main property is the ability to react reversibly with cations at respective reaction zone and to diffuse throughout the liquid membrane phase in its salt ( $C_2A$ ,  $C_2B$ ) or acid (CH) form. It is also assumed that ionic species or their ionic pairs cannot diffuse in membrane phase without the carrier intervention. The membrane is formally divided into  $n$  homogeneous compartments, which contains the carrier in the form  $C_2A$ ,  $C_2B$ , and CH the local concentration of which are equal to  $[C_2A]_k$ ,  $[C_2B]_k$ , and  $[CH]_k$ , with  $k = 1, 2, \dots, n$ . In the case of bulk agitated or flowing liquid membranes, the model should be modified by adding a large central compartment (layer) acting as an additional capacitor enabling convective flow of the membrane liquid.

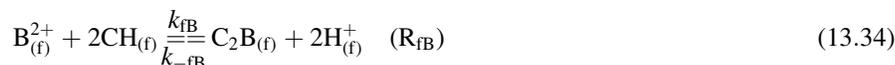

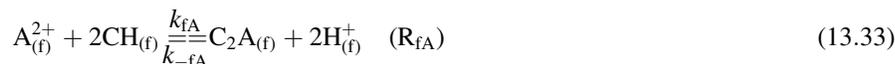

The following are the assumptions of the model:

1. Concentrations of ionic species within interfacial reaction layers of thickness  $L_f$  and  $L_s$  are the same as in the feed or stripping solution, respectively.
2. Concentrations of cations bound by the carrier at respective interfacial layer, i.e.,  $[C_2A]_i$ ,  $[C_2B]_i$ , and  $[CH]_i$  with  $i = f$  or  $s$ , are the same as the concentrations in the membrane compartments indexed by  $k = 1$  or  $n$ .
3. Interfacial carrier molecules are presented by their hydrophilic fragments in adjacent aqueous solutions and by their hydrophobic parts in an organic phase of a liquid membrane. Thus, the reaction can be treated as a homogeneous type occurring in an adjacent reaction zone instead of a heterogeneous adsorption-type reaction process.
4. Initial concentration of the carrier is the same as in a bulk liquid membrane phase.
5. Concentration of free cations is the same as in the bulk aqueous phase.
6. Thermodynamic couplings between transported species are negligible.

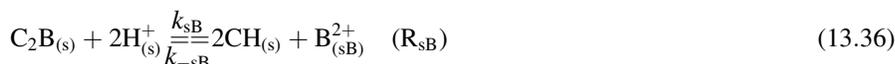

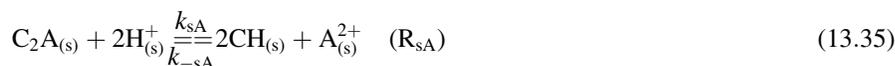

At these assumptions and simplifications the thermodynamic network analysis (TNA) [90] can be applied to analyze LM transport. Certainly in the case of a real specific system, the detailed mechanism of reaction–diffusion interfacial phenomena should be taken into account as far as possible. The above assumptions allow maintaining a concept of a homogeneous reaction. Any universal model does not exist, and in the description of a real membrane process the accessible knowledge concerning the specific interfacial processes should be taken into account. The model presented can be regarded as a simplified example only.

According to the scheme presented in Figure 13.4, two competitive cation-exchange processes occur at each of the interfaces:

At the feed interface

At the strip interface

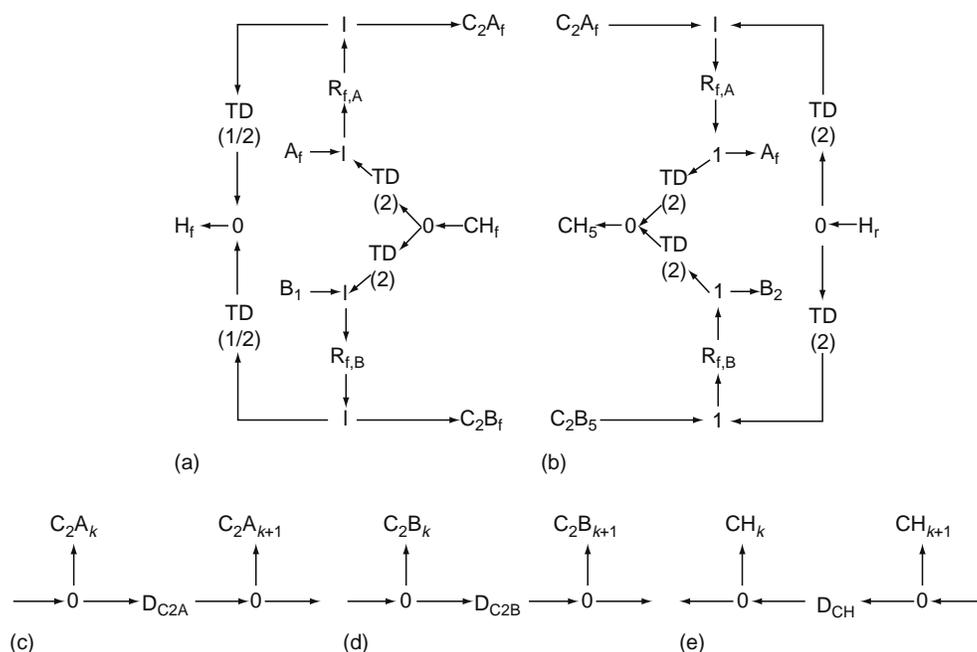

The reactions between the carrier and the two cations cannot be considered as parallel because  $A^{2+}$  and  $B^{2+}$  compete toward the same carrier or the respective carrier forms compete in the reaction with a stripping agent. Thus, the respective reaction rates are represented by coupled differential equations resulting from networks in Figure 13.6.

The symbols  $k_{i,M}$  and  $k_{-i,M}$  ( $i = f, s, M = A, B$ ) denote the kinetic constants for the rates of reversible reactions given by Equations 13.37 through 13.40:

$$J_{f,A} = k_{f,A}[A]_f[CH]_f^2 - k_{-f,A}[C_2A]_f[H]_f^2 \quad (13.37)$$

$$J_{f,B} = k_{f,B}[B]_f[CH]_f^2 - k_{-f,B}[C_2B]_f[H]_f^2 \quad (13.38)$$

**FIGURE 13.6** Network for feed (a) strip, (b) competitive cation-exchange reactions, and local diffusion processes: (c)  $C_2A$ , (d)  $C_2B$ , and (e)  $CH$  species. (From Wodzki, R., Szczepanska, G., and Szczepanski, P., *Sep. Purif. Technol.*, 36, 1, 2004. With permission.)

$$J_{s,A} = k_{s,A}[C_2A]_s[H]_s^2 - k_{-s,A}[CH]_s^2[A]_s \quad (13.39)$$

$$J_{s,B} = k_{s,B}[C_2B]_s[H]_s^2 - k_{-s,B}[CH]_s^2[B]_s \quad (13.40)$$

According to the scheme of the compartments in the liquid membrane system in Figure 13.5b, all local diffusion fluxes of M species from  $k$  to  $k + 1$  compartment can be defined by a phenomenological Equation 13.41 corresponding with the first Fick's law for diffusion:

$$N_{j(k,k+1)} = P_j \Delta[X]_{j(k,k+1)} \quad (13.41)$$

where  $P_j$  denotes the permeability coefficient of species (e.g., carrier in different forms) between  $k$  and  $k + 1$  compartment:

$$P_j = D_j S / (L_m / n) \quad (13.42)$$

In Equations 13.37 through 13.41  $\Delta[X]_{j(k,k+1)}$  denotes the concentration difference, between the compartment  $k$  and  $k + 1$ , for the carrier transporting cation  $j$  ( $j = A^{2+}, B^{2+}, H^+$ ) with the diffusion coefficient  $D_j$ . Consequently, the diffusion coefficients of a carrier transporting different cations are different but constant throughout the liquid membrane (independent of their local concentration).

To construct the pertraction network, the particular reaction networks should be added via "0" junctions to three linear networks corresponding with the processes of diffusion of  $C_2A$ ,  $C_2B$ , and  $CH$  carrier species. The resulting reaction-diffusion network, as presented in Figure 13.6, consists of four coupled loops representing the pertraction of  $A^{2+}$ ,  $B^{2+}$ , and  $H^+$  cations. The loops are coupled by common capacitances  $A_i$ ,  $B_i$ , and  $H_i$  ( $i = f, s$ ) and by the capacitances  $CH_i$  and  $CH_k$  for a reacting or diffusing acidic form of the carrier. From the network in Figure 13.6, all the model equations used further in numerical calculations can be deduced with the help of Kirchhoff's law for a 0 junction (KCL):

$$\sum_k v_k N_k = 0 \quad (13.43)$$

where

$k$  is the index of the flux entering or leaving a given 0 junction

$v$  is  $\pm 1$  valued depending on the bond direction

Note that all the reactions and diffusion rates should be expressed in moles per second to maintain the compatibility of units.

The mathematical model derived from the network in Figure 13.6 together with the specification of all the local fluxes, time-dependent variables, and parameters is presented in Table 13.1. The model consists of ordinary differential equations (ODE) describing the evolution of all capacitances (local concentrations) characteristic for a membrane and external solutions.

A step-by-step simulation of the system can be carried out by numerical calculations when the initial values of capacitances and the values of parameters (constants) are assigned. The calculations have been performed using the model from Table 13.1 after assuming  $n = 4$ . This value is sufficient [86] to achieve reliable simulation data of typical liquid transport processes under study. However, it should be noted that the increase in the number of layers, i.e., increasing in  $n$  will always result in more precise calculations and predictions comparable to those achieved by analytic calculation methods. The  $n$ -value equal to 4 should be treated as the lowest limit required for obtaining quantitative data sufficient for the interpretation of the separation effects. The problem of proper compartmentalization can be especially significant when reactions locally attain quasi-equilibrium conditions.

The Madonna Berkeley (ver.3) solver of ODE, the set of parameters, and initial conditions describing a liquid membrane system (listed in Table 13.2) were applied to numerically investigate the properties of CPS. The main relations resulting from the computations were time-dependent values of (1) the concentration profiles of transported and antipported species in a liquid membrane, (2) the concentration of  $A^{2+}$  and  $B^{2+}$  in the external aqueous solutions, and (3) input and output fluxes of  $A^{2+}$  and  $B^{2+}$ . To characterize the membrane selectivity toward the target  $A^{2+}$  cations, the following quantities are calculated and discussed.

The selectivity ( $S_{N,i}$ ) is calculated as the ratio of  $A^{2+}$  and  $B^{2+}$  fluxes ( $N$ ) for feed (f) and strip (s) interface, henceforth it is called as input or output flux selectivity:

$$S_i = N_{A,i} / N_{B,i}, \quad i = f \text{ or } s \quad (13.44)$$

The overall separation factor ( $\alpha_B^A$ ):

$$\alpha_B^A = \frac{[A]_s[B]_f}{[B]_s[A]_f} \quad (13.48)$$

The above quantities are accessible by standard measurements of liquid membrane transport and are frequently reported in the corresponding literature. To emphasize the kinetic source of separations studied, all computations have been carried out after assuming the same equilibrium constants for cation-exchange reactions appearing in the pertraction system, i.e.,

$$K_{f,A} = K_{f,B} = k_{f,A}/k_{-f,A} = k_{f,B}/k_{-f,B} \quad (13.49)$$

$$K_{s,A} = K_{s,B} = k_{s,A}/k_{-s,A} = k_{s,B}/k_{-s,B} \quad (13.50)$$

The conditions (Equations 13.49 and 13.50) impose no selectivity for the CPS under stationary conditions when the reactions attain their equilibrium state and the diffusion coefficients  $D_{C2A}$  and  $D_{C2B}$  are equal.

The bond-graph network of liquid membrane process can be successfully exploited for modeling the separation and transport ability of complex reaction–diffusion phenomena. However, it should be stated that such models involving appropriate mathematical formulations are especially useful in predicting the system's response to the changes in operating conditions and specific characteristics of the liquid membrane components. In general, such models are not applicable for the assessment of unknown parameters. The idea of network modeling needs as much information as possible to be introduced into a model. Thus, at the initial step no factor can be ignored though it is common in many other phenomenological descriptions assuming diffusion- or reaction-limited conditions. Consequently, the related calculations should be treated as experiments aimed at searching for new quantitative differences in transport and separation systems rather than numerical interpretations of the data that possibly explain the known experimental facts.

### 13.2.3 THEORY OF HOLLOW-FIBER LIQUID MEMBRANE TRANSPORT [5,9–11,38,62,63,91–93]

The theory of a hollow-fiber contained liquid membrane (HFCLM) transport is described in detail by Sirkar et al. in Refs. [58,59,91]. Its modified model, (HFLM), developed by Schlosser et al. [5,9–11,25,38,92] is presented below.

Concentration profiles of a solute in three-phase system transport through LM in a hollow-fiber module are similar to that, presented in Figure 13.3.

Following assumptions are held [11,25]:

1. Steady-state flux.
2. Consider only diffusional resistances,  $R_i$ . Reactions on both interfaces are fast and negligible accumulation in boundary layers is supposed.
3. High stoichiometric excess of reactant in the stripping solution.
4. Fibers are identical and the number of fibers in both bundles (for feed and strip solutions) is the same.

$$S_{wF} = S_{wR} = S_w; \quad \varepsilon_F = \varepsilon_R = \varepsilon; \quad \tau_F = \tau_R = \tau; \quad \text{and } k_{wF} = k_{wR} \quad (13.51)$$

where

- $S_{wF}$ ,  $S_{wR}$ , are surface area (square meters), in the feed and strip
- $\varepsilon$  is porosity of the fiber
- $\tau$  is tortuosity of the pores
- $k_i$  are individual mass transfer coefficients,  $\text{m s}^{-1}$

This results concentration of solute in the feed referring to its concentration in the strip,  $C_{FRM}$ , equal zero:

$$C_{FRM} = C_R * D_R / D_F = 0 \quad (13.52)$$

and

$$R_R = 0 \quad (13.53)$$

where

- $C_i$  are the molar solute concentrations
- $D_i$  are distribution coefficients at equilibrium at feed-membrane and membrane-strip interfaces

Relation for the overall mass transfer resistance can be derived [11,25,91]:

$$\frac{1}{K_p} = \frac{\varepsilon_F}{k_F} + \frac{S_F}{DS_{wF}k_{wF}} + \frac{S_F\varepsilon_F}{DS_Mk_M} + \frac{S_F\varepsilon_F}{DS_{wR}\varepsilon_Rk_{wR}} + \frac{S_F\varepsilon_F}{S_Rk_R} \quad (13.54)$$

$$R = R_F + R_{wF} + R_M + R_{wR} + R_R \quad (13.55)$$

Identification of the individual mass transfer coefficients depends on the construction of the module (material and structure of fibers in both bundles) and on the way of its operation. For the laminar flow inside hollow fibers, the following correlation can be used [93]:

$$\frac{k_F d_i}{D_f} = 1.5 \left( \frac{d_i^2 u_F}{L D_f} \right)^{1/3} \quad (13.56)$$

where

$d_i$  is the fiber diameter (m)

$D_f$  is diffusion coefficient ( $\text{m s}^{-1}$ )

$u_i$  is linear velocities of flow ( $\text{m s}^{-1}$ )

$L$  is the effective length of the fibers (m)

Individual mass transfer coefficients in the pores are estimated by equation

$$k_w = k_{wF} = k_{wR} = \frac{2D_{FM}}{\tau(d_0 - d_i)} \quad (13.57)$$

and

$$R_{wF} = R_{wR} = R_w \quad (13.58)$$

The resistance in the BLM is calculated from equation:

$$R_M = R - (R_F + 2R_w) \quad (13.59)$$

Differential mass balance of solute in the feed stream along the length of the HF contactor for constant volumetric flow rates of the solutions is

$$-V_F \frac{dC_F}{dz} = K_{ploc} (\pi * d_{iF} N_F \varepsilon_F) (C_F - C_{FRM}) \quad (13.60)$$

where

$V_i$  are volumes of the solution passed

$K_{ploc}$  is defined for effective surface area of the feed/LM interface

In cases when concentration  $C_{FRM}$  is close to zero, after rearranging of Equation 13.60:

$$K_{ploc} dz = - \frac{V_F}{\pi d_{iF} N_F \varepsilon_F} \frac{dC_F}{C_F} \quad (13.61)$$

Integrating Equation 13.60 for initial and boundary conditions,  $z=0$ ,  $C_F = C_{F1} = C_{F0}$ , and for  $z=L$ ,  $C_F = C_{F2}$  the following relation is obtained:

$$L = \frac{V_{F0}}{K_p \pi d_{iF} N_F \varepsilon_F} \ln \frac{C_{F0}}{C_{F2}} \quad (13.62)$$

and the concentration of the solute in the strip,  $C_{F2}$  can be calculated by equation:

$$\frac{C_{F2}}{C_{F0}} = \exp [-(\pi d_i N_F / V_F) (K_p L)] \quad (13.63)$$

where  $K_p$  is the integral value of the overall mass transfer coefficient of the module.

These considerations and the set of equations for transport of the solute through the HF modules are modified and simplified in comparison to the HFCLM [91] theoretical considerations. The models presented in Sections 13.2.1 and 13.2.2 consider more detailed diffusion parameters at the F/LM and LM/R interfaces, more detailed kinetics of chemical reactions. So, they are more identical to the real transport processes, therefore, these models, modified for a hollow-fiber permeator, may be used for the hollow-fiber transport also.

### 13.3 MODULE DESIGN FOR SEPARATION SYSTEMS

Technological complexity of ELM and problems with the stability of SLM has led researchers in the recent years to look for alternative BLM or organic (water-immiscible) LM. A big number of OHLM (or BLM) separation systems are described in the literature. They can be divided according to type of membrane walls (barriers) used: planar, spiral wound and hollow fiber, and to hydrophobic/hydrophilic properties of the membrane. The hydrophobic membranes are immobilized by LM organic solutions and hydrophilic or ion-exchange membranes are immobilized by aqueous feed and strip solutions.

Hydrophilic (or ion-exchange) membranes were used for designing rotating disc, creeping film, HLM, and MHSs, HFLM modules. Hydrophobic membranes were used for designing HLM, MHS, FLM, HFCLM, and capillary liquid membrane modules. Below, some of these systems are referenced and described shortly.

#### 13.3.1 LAYERED BULK LIQUID MEMBRANE MODULES [55,94]

The simplest U- or H-shaped layered BLM modules, without membrane walls, are used mainly in transport studies [55,94]. Examples of BLM-layered module with mixing all three solutions are presented in Figure 13.7.

#### 13.3.2 ROTATING DISC MODULES [12,14,16,18,20,95–103]

As seen in Figure 13.8, hydrophilic membrane discs are fixed on a horizontal shaft and their lower parts are immersed to compartments, which are filled with the feed and strip solutions. The remaining parts of the discs, in which aqueous phases (feed or strip) are immersed, due to rotation, are in contact with the LM phase. Mass transfer of the solute from the feed into the strip solutions occurs through the BLM phase.

Contactors with two parallel shafts with discs, one for the feed and one for the strip solutions are presented in the Ref. [96].

#### 13.3.3 CREEPING FILM MODULES [19,21,22,58,104–107]

Creeping film process (CFP) is a liquid membrane technique for simultaneous removal and concentration of dissolved species from their diluted aqueous solutions. CFP contactor is presented schematically in Figure 13.9. Feed and strip solutions flow down the vertical hydrophilic porous membrane sheets. A mobile organic LM is interposed between two creeping aqueous films. CFP is a continuous mass transfer process in which eddy diffusion controls the mass fluxes in all three liquid films.

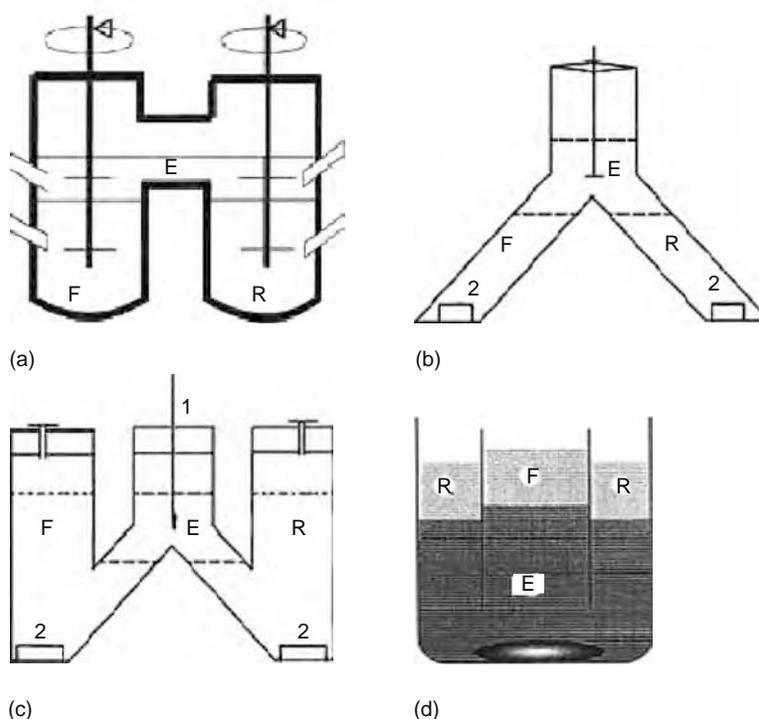

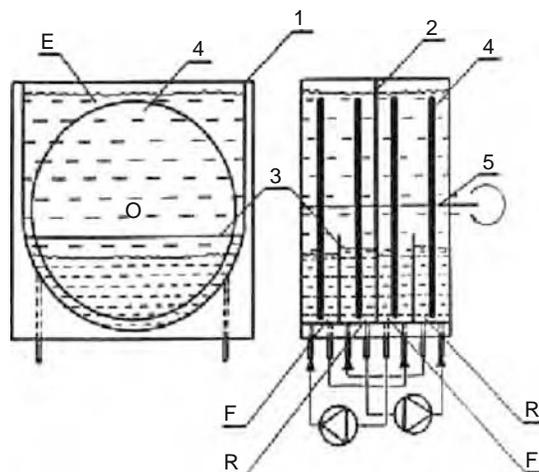

FIGURE 13.7 Examples of layered BLM modules.

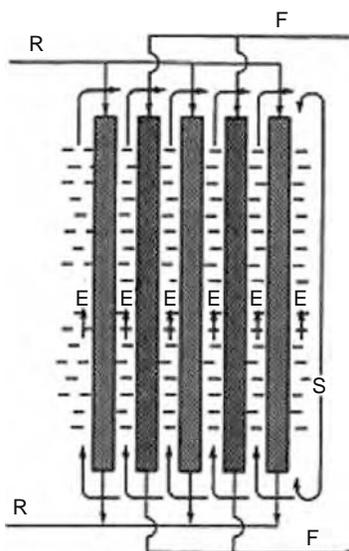

**FIGURE 13.8** Scheme of a rotating film contactor: (1) body; (2) stage wall; (3) feed/stripping solution separating walls; (4) rotating discs; (5) common shaft. (From Zhivkova, S., Dimitrov, K., Kyuchoukov, G., and Boyadzhiev, L., *Sep. Purif. Technol.*, 37, 9, 2004. With permission.)

### 13.3.4 HYBRID LIQUID MEMBRANE MODULES [1–3,40,43,44]

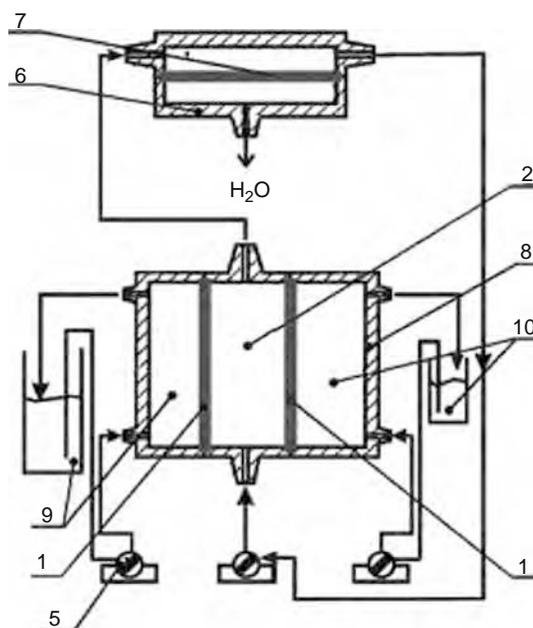

Figure 13.1 represents schematically different types of HLM contactors. A liquid membrane solution flows (or circulates) between two membranes, which separate the LM phase (E) from the feed (F) and receiving (R) phases. A solute (or solutes) diffuses to the F/E interface and is extracted from feed phase by a carrier as a result of the thermodynamic conditions at the F/E interface. The solute–carrier complex diffuses to the E/R interface and is simultaneously stripped by the receiving phase due to the different thermodynamic conditions at the E/R interface. The membranes may be hydrophobic, immersed by LM, or hydrophilic (or ion exchange), immersed by feed and strip aqueous phases.

### 13.3.5 MULTIMEMBRANE HYBRID SYSTEMS [29,47,51,56,108]

MHS with pervaporation of water from LM (MHS-PV) is presented in Figure 13.10. Contrary to the simple MHS with an agitated BLM, separated from the feed and strip solutions by flat hydrophobic or hydrophilic or ion-exchange membranes, the MHS-PV system exploits an FLM continuously flowing between the two flat cation-exchange and two pervaporation membranes. To couple the separation and pervaporation processes, the LM is simultaneously pumped through the MHS and

**FIGURE 13.9** Scheme of a creeping film contactor: F, R—inlet and outlet of the feed and receiving solutions, respectively; E—FLM organic solution. (From Boyadzhiev, L. and Lazarova, Z., *Chem. Eng. Sci.*, 42, 1131, 1987. With permission.)

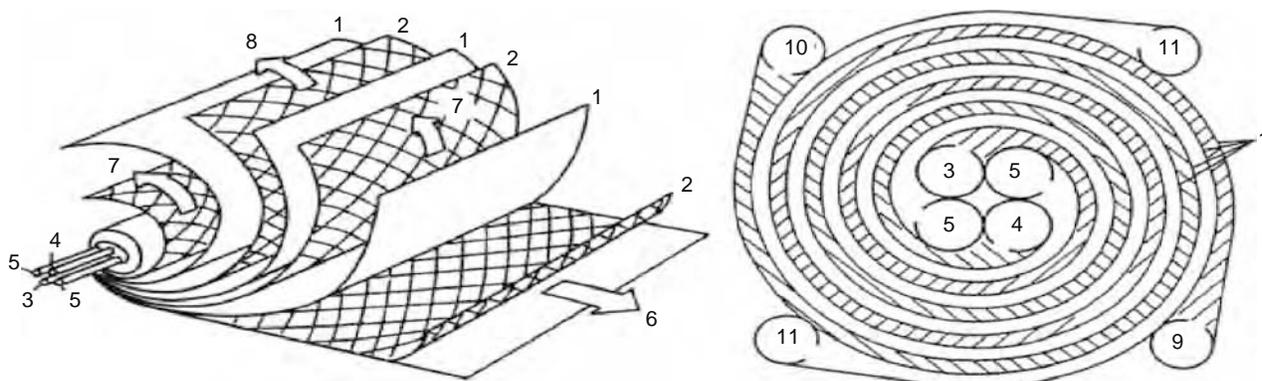

**FIGURE 13.10** Scheme of the MHS[FLM-PV] multimembrane hybrid system: (1) cation-exchange membranes, (2) FLM, (5) vacuum system, (6) pervaporation unit, (7) pervaporation membranes, (8) contactor, (9) feed solution, (10) stripping solution. (From Wodzki, R. and Szczepanski, P., *J. Mem. Sci.*, 197, 297, 2002. With permission.)

PV modules. The pervaporation membranes are placed on a stainless steel porous supports. Aqueous feed and strip solutions are intensively agitated. The MHS (without pervaporation section) and HLM are very similar systems.

### 13.3.6 FLOWING LIQUID MEMBRANE MODULES [19,30,33–36,109]

In FLM, the LM organic solution flows in a thin channel between two hydrophobic microporous membranes separating the LM phase from an aqueous feed and strip solutions. The FLM differs from the HLM and MHS modules with hydrophobic membranes by application of a spiral-type module. A schematic diagram of the spiral-type FLM module is shown in Figure 13.11.

The microporous membrane films (see Table 13.3) and one mesh spacers were spirally wound around acrylic resin pipes through which the feed, strip, and organic LM solutions were supplied to the module [34,36]. The outer surface and the top and bottom ends of the module were sealed with an adhesive.

**FIGURE 13.11** Schematic diagram of a spiral-type flowing liquid membrane module: (1) microporous hydrophobic membrane, (2) mesh spacer, (3) inlet and (9) outlet pipe of feed, (4) inlet and (10) outlet pipe of strip, (5) inlet and (11) outlet tube of organic membrane solution, (6) feed solution, (7) organic LM solution, and (8) strip solution. ### 13.3.7 HOLLOW-FIBER LIQUID MEMBRANE MODULES [4–6,9–11,38,104]

Several types of three-phase hollow-fiber (HF) modules have been described. They can be classified into two groups. The first one with parallel phase flow was developed by Sirkar group, termed as a “hollow-fiber contained liquid membrane” (HFCLM) and described in detail in Ref. [4]. The HFCLM module was used for separation of solutes in liquids and gases. Another type of HF modules, developed by Schlosser group, “hollow fibers in tube pertractor” with parallel flow [10,11,23–26,55,104] consists of one or two intermixed U-shaped bundles of microporous polypropylene fibers, inserted into polysulfon (or glass) tubes (see Figure 13.12). For a better mixing, pulsation of the LM phase along the fibers is used. It increases the transport rate by 35%–60%.

**FIGURE 13.12** Scheme of the hollow-fiber contactor with parallel flow of phases, distributed U-shaped bundles of fibers and with separated inlet and outlet end chambers. F: feed (donor phase), E: liquid membrane phase, R: stripping solution, (1) hollow fiber for the feed, (2) glass tubulet, (3) glass tempering jacket of the contactor. (From Schlosser, S. and Sabolova, E., *J. Mem. Sci.*, 210, 331, 2002. With permission.)

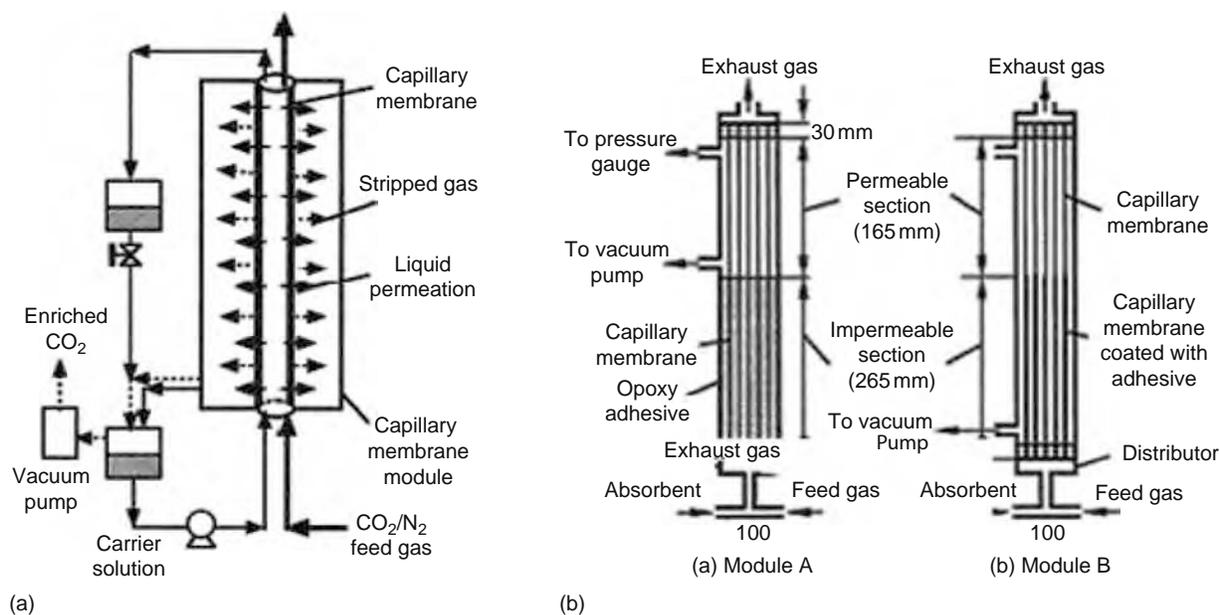

**FIGURE 13.13** Scheme of the hollow-fiber contactor of three phases with cross flow of LM phase: (1) body of element, (2,3) hollow fiber in downstream and upstream part, (4,5) inlet and outlet chamber, (6,7) inlet and outlet tube, (8) flowing head, and (9) central baffle, F: feed, E: LM phase, R: strip solution. (From Schlosser, S., Pertraction through liquid and polymeric membranes. In: Belafi-Bako, K., Gubicza, L., and Mulder, M. Eds. *Integration of Membrane Processes into Bioconversions*. Proceedings of the 16th European Membrane Society Annual Summer School. Veszprem, Hungary, August 1999. Kluwer Academic/Plenum Publishers, New York, 2000, 73–100. With permission.)

The second type of the HF modules has also been developed by Schlosser group [25,38–40,92,104]. This module enables a cross flow of the liquid membrane phase or its pulsation perpendicular to fibers, as shown in Figure 13.13. The planar HF elements can be assembled for contacting four or more phases.

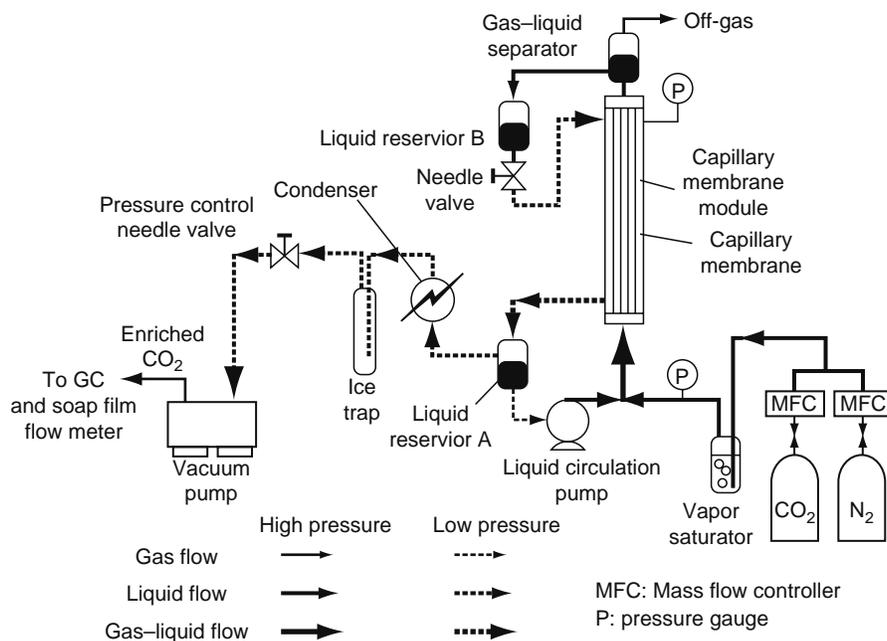

Some modified plate and frame HF modules [110–112] were proposed. Both ends of fibers were potted on opposite sides of the frame-forming elements of the stack. The transversal flow of one phase was possible. The module with “fiber in fiber” units and cross flow of one phase is described in Ref. [9].

### 13.3.8 CAPILLARY LIQUID MEMBRANE SYSTEMS [113–115]

Facilitated transport for gas separation using a capillary membrane module was developed by Teramoto group [113,114]. Concept of capillary membrane apparatus is shown in Figure 13.14. Both an feed gas and an LM solution are supplied to the

**FIGURE 13.14** Schematic diagrams of facilitated transport of gas using capillary membrane module for removal and enrichment of carbon dioxide. (a) Experimental capillary membrane apparatus and (b) capillary membrane modules with permeation of carrier solution. (From Teramoto, M., Ohnishi, N., Takeuchi, N., et al., *Sep. Purif. Technol.*, 30, 215, 2003. With permission.)

**FIGURE 13.15** Schematic diagram of experimental setup with capillary membrane for simultaneous removal and enrichment of CO<sub>2</sub>. (From Teramoto, M., Kitada, S., Ohnishi, N., et al., *J. Mem. Sci.*, 234, 83, 2004. With permission.)

lumen side (high-pressure feed side) of the capillary ultrafiltration membrane module and flow upward. The LM solution, which contains dissolved solute gas (CO<sub>2</sub> in the present case), flows to the permeate side (low pressure, shell side), where the solution liberates dissolved gas to become a lean solution. The lean solution is returned to the lumen of the capillary module by a pump. In the shell side, dissolved gas is stripped from the liquid flowing down the outer surface of the capillary, and discharged from a vacuum pump through a liquid reservoir. Schematic diagram of experimental setup is shown in Figure 13.15.

Mixtures of CO<sub>2</sub> (5%–15%) and N<sub>2</sub> were used as model feed gas, and monoethanolamine (MEA), diethanolamine (DEA), and 2-amino-2-methyl-1-propanol (AMP) were used as the carriers of CO<sub>2</sub>. The polyethersulfone capillary ultrafiltration membranes (see Table 13.4) were used in the module. The membrane was very stable over a discontinuous 4-month testing period. The energy consumption was found to be much smaller than those of conventional chemical absorption and membrane separation processes.

### 13.3.9 MEMBRANE TYPES USED

Most membranes, used as a wall between phases in the OHLM systems, are polymeric although inorganic membranes have also become available. Membranes can be classified according to structure as homogeneous, asymmetric, or composite, according to geometry as flat sheet, hollow fiber, or tubular, according to pore surface as neutral hydrophobic or hydrophilic and surface

<sup>a</sup> Not available in manufacturer's catalog.

charged (ion exchange). Hydrophobic membranes, flat sheet, or hollow fibers, (see Tables 13.3 and 13.4) are readily moistenable by most organic solvents, but water does not moisten it. An organic solvent, brought on one side of the membrane, immediately wets the membrane and appears on the other side, or immobilizes the interface. Aqueous solution to be contacted with the organic solution of a carrier is brought at a pressure higher than that of organic solution to prevent the latter from coming through the membrane, but not so high to be able to displace organic phase from inside the pores completely. The two phases contact each other at a mouth of the pores or inside the membrane (see Figures 13.1a, 13.1d, and 13.3).

On the contrary, hydrophilic and ion-exchange membranes (see Tables 13.3 through 13.5) are readily wettable by aqueous solutions, but immiscible by organic phases. So, contact between aqueous and organic phases takes place on the other side to the bulk aqueous phase interface of the membrane (see Figures 13.1b, 13.1e, and 13.4).

Although several inorganic ion-exchange materials (zeolites, bentonites) are now available, most membranes used are polymeric. The properties of ion-exchange membranes are closely related to those of ion-exchange resins. The properties, important for the separation reasons, are permselectivity, long-term electrical (resistance) and chemical stability, and ion-exchange capacity (see Table 13.5). Flat sheet, hollow fiber, and tubular ion-exchange membranes are available.

The limits of pore dimensions in OHLMs are purposely chosen to minimize convective transport. Two solutes can be separated if their diffusion coefficients differ by at least an order of magnitude. This diffusivity is modified by the matrix structure and pore size of the membrane. Knowledge of the relative solute diffusivities in the membrane gives us the knowledge of retention abilities of the membrane. The sieving properties of the membranes allow them to retain some macromolecules while selectively removing solutes of middle molecular weight and less selective removal of solutes with small molecular weight.

The knowledge of the difference between solute diffusivities in the membrane, immobilized by organic phase (hydrophobic), vis-à-vis the membrane, immobilized by aqueous phase (hydrophilic, ion exchange), would aid in the choice of membrane type. In all cases, the membrane material would have to be completely long-term resistant to the solvents of either phase.

The first choice would be to use a membrane as thin as possible, with high porosity, and small pore size, while still providing the mechanical stability for potting and pumping pressure.

## 13.4 SELECTED APPLICATIONS

Applications of the OHLM processes are tested mainly in metal separation, wastewater treatment, biotechnologies, drugs recovery-separation, organic compounds, and gas separation. In the recent years, integrated hybrid systems incorporating two or more functions in one module, for example biotransformation and separation, become systems of great interest to researchers. The recent applications of different types of the OHLM systems are summarized below.

### 13.4.1 METAL SEPARATION-CONCENTRATION

Metal ions separation for hydrometallurgical applications has attracted considerable interest. Selective separations of alkali, alkali earth, heavy metal ions, rare earth, precious metals, etc. are studied by many authors using all the above-described techniques. Referenced works in metal separations classified according to the OHLM techniques with types of membrane walls and carriers used are listed in Table 13.6.

### 13.4.2 BIOTECHNOLOGICAL PRODUCTS RECOVERY-SEPARATION

Recovery from fermentation broth and separation of carboxylic acids, amino acids were tested by many authors using layered BLM, rotating, creeping, spiral-type FLM, HFLM, HLM, and MHS-PV techniques of the OHLM processes. The research works for the last 15 years in this field classified according to the OHLM techniques with types of membrane walls and carriers used are provided in Table 13.7.

### 13.4.3 PHARMACEUTICAL PRODUCTS RECOVERY-SEPARATION

Selected papers for the last 15 years, presenting results of separation of drugs, antibiotics, enantiomers by layered BLM, HFLM, rotating film techniques are listed in Table 13.8. Hollow-fiber contactors, developed modular elements with optimum-configured stacks for individual applications may be an interesting direction in research.

### 13.4.4 ORGANIC COMPOUNDS SEPARATION, ORGANIC POLLUTANTS RECOVERY FROM WASTEWATERS

Separation of ethylene, benzene, propanol, olefin, aromatic amines from organic liquid mixtures, of volatile organic compounds (VOC), and phenol from wastewater, were investigated by the authors (Table 13.9), using rotating film module,

spiral-type FLM, hollow fiber and layered LM techniques. High separation factors (>1000) in pilot and industrial scale experiments were found.

#### 13.4.5 GAS SEPARATIONS

Oxygen transport via a hemoglobin carrier was one of the first LM transport systems [53]. It was noted that the rates of complex formation and reversal were very important.

Carbon dioxide separation from the air, mixtures with CH<sub>4</sub>, N<sub>2</sub>, O<sub>2</sub>, has been studied from both biological and engineering applications. Spiral-type FLM, HFLM, and capillary membrane techniques were tested for these purposes.

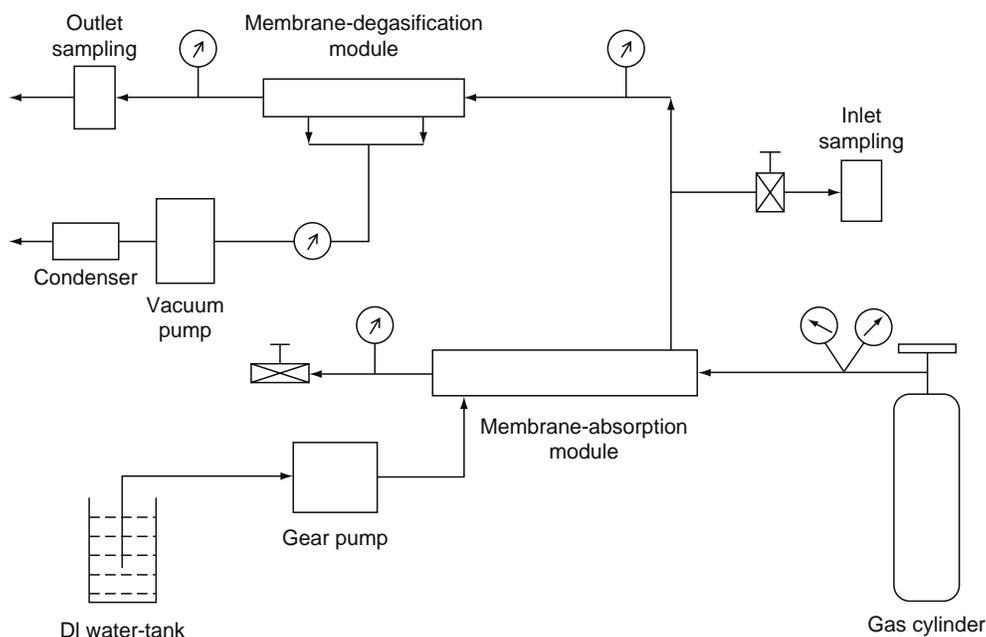

Hydrogen sulfide and sulfur dioxide removal were studied using HFLM technique for coal gasification applications.

References of the works carried out in the field of gas separations are presented in Table 13.10.

Schematic diagram of experimental setup for gas separation and enrichments is shown in Figure 13.16.

### 13.4.6 FERMENTATION OR ENZYMIC CONVERSION-RECOVERY-SEPARATION (BIOREACTORS)

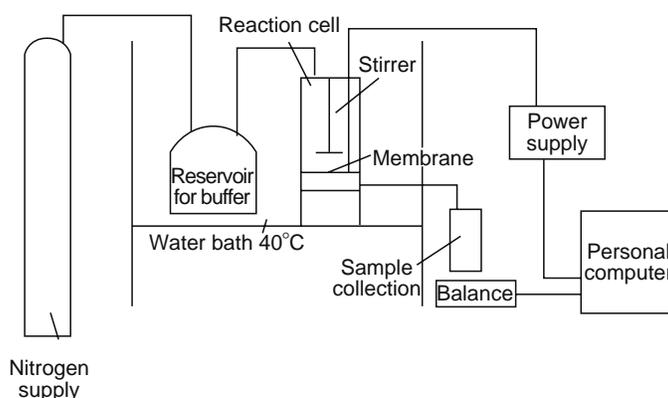

The OHLM systems, integrating reaction, separation, and concentration functions in one equipment (bioreactor), find a great interest of researchers in the last few years. A bioreactor combines the use of specific biocatalyst for the desired chemical reactions, and repeatedly or continuously application of it under very specific conditions. Such techniques were termed as hybrid membrane reactors. In biotechnology and pharmacology, these applications are termed as hybrid membrane bioreactors or simply bioreactors (see Table 13.11). Experimental setup of the bioreactor system is shown schematically in Figure 13.17.

### 13.4.7 ANALYTICAL APPLICATIONS

OHLM techniques were used in analytical methods for separation and preconcentration of metals [252–254], organic acids [255,256], and organic and pharmaceutical compounds [257–261]. Preparation of the samples for analytical purposes seems to be one of the perspective directions in application of the OHLM processes.

### 13.5 CONCLUDING REMARKS

In comparison with LLX, SLM, and ELM, the OHLM has the potential of providing many economic and operational advantages such as low-carrier losses, long membrane lifetime, “once through” continuous operation, compact equipment, application of different driving forces (chemical potential, pressure, temperature gradients between different compartments, electric field, etc.), no need of surface formation, impregnation, gravity gradients, high membrane capacity, etc. Commercially available membrane modules and equipment may be used in the OHLM.

Currently, only commercial application of the LM technologies is wastewater treatment (water and degasification), where low concentration solutes are removed from large volume of effluents. Solvent extraction and ion exchange are often not economically convenient at these cases. Due to the complexation reaction and low quantity of complexing agent-carrier required, the OHLM technologies are suited for high recoveries of dilute solutes. LMs are used commercially in production of ion-selective electrodes and gas sensors selective for organic vapors.

Despite promising technological performance, few OHLM techniques have been commercialized. This fact stems from many economic and technical factors. The main drawbacks of the OHLM systems observed are the poisoning of the carrier by irreversible reactions, low-diffusion rate of the large organic molecules, losses of the LM and contamination of the treated and product aqueous solutions by the LM organic components due to the leakage, the membrane walls blinding or fouling due to the emulsion, and gel formation on their surfaces. Long-term stability of complexing agent-carriers in the LM, stability of membrane walls, and their long-term permeability are the problems that limit the commercialization of the OHLM technologies.

It is necessary to develop complexation chemistry and new selective carriers or to improve existing ones for improving separation and transport properties, required to optimize the OHLM processes.

Improving and reducing the price of membrane film or hollow-fiber production will definitely speed industrial application of the OHLM technologies, especially in gas, pharmaceutical, and bioreactor applications.

### NOMENCLATURE

7-ACA	7-aminocephalosporanic
AMP	2-amino-2-methyl-1-propanol
6-APA	6-aminopenicillanic acid
Cyanex 302	di-(2,4,4-trimethyl-pentyl) monothiophosphinic acid, a product of CYTEX Canada Inc. (nowadays Cognis)
Cyanex 471x or TIBPS	triisobutylphosphine sulfide
DB18C6	dibenzo-18-crown-6
DEA	diethanolamine
DEHPA	di-(2-ethylhexyl) phosphate
DMCCA	dimethyl(cyclopropane)carboxylic acid
EHPNA	2-ethylhexyl phosphonic acid, mono-2-ethylhexyl ester (PC-88A), Daihachi Chemical Industry Co., Ltd. Japan
Hostarex A 327	<i>n</i> -octyl( <i>n</i> -decyl)amine
MDEA	methyl-di-ethanol-amine
MEA	monoethanolamine

MEHPA	(2-ethylhexyl) phosphate ( $C_8H_{19}O_4P$ ), containing 45% of mono-(2-ethylhexyl) phosphate on molar basis
MAs	mandelic acids
PAA	phenylacetic acid
PABA	<i>p</i> -aminobenzoic acid
Star-shaped polymer	$[CH_3O(CH_2CH_2O)_n]_x$ -[DGEEG]- $[(CH_2CH_2O)mP(O)(ONa)_2]_x$ , (MPOE-[DGEEG]-POEP), (DGEEG is ethylene glycol diglycidyl ether)
PPOPP	poly[poly(oxypropylene) phosphate]s, ( $M_n = 5,800, 8,100, 10,400$ ), with different POP units (400, 1,200, 2,000)
PEG 4000 and 6000	poly(ethylene glycol)
PPG, PPO	poly(propylene glycol)
MPOEP	methoxy-poly(oxyethylene) phosphate (1)
POEBP	poly(oxyethylene) bisphosphate 2, poly(oxyethylene) bis(di-Me phosphate), 3
POEBMP	poly(oxyethylene) Me ether phosphate
POEP	poly(oxyethylene) phosphate
PEGP	poly(ethylene glycol) phosphate
TBP	tri- <i>n</i> -butylphosphate
THP	tri-hexylphosphate
TOA	tri- <i>n</i> -octylamine
TOMAC	tri-(octylmethyl) ammonium chloride
TOPO	tri- <i>n</i> -octylphosphinic oxide

## 14.1 MEMBRANE TECHNOLOGIES

Filtration- and membrane-based separation operations are used in the manufacture of many pharmaceutical products. These operations range, for example, from the clarification of fermentation broths used in the production of antibiotics, to virus clearance for plasma-derived protein therapeutics, to sterile filtration of heat-labile products, and beyond. Innovations in membrane materials and module design allow membranes to be used in an increasingly wider range of manufacturing steps. This chapter describes different membrane technologies and their applications during the manufacture of pharmaceutical products such as antibiotics, plasma-derived proteins, active pharmaceutical ingredients, and parenterals (small and large volume).

Membranes are selective barriers that allow for the transmission of certain feed components while retaining other components. The mechanism behind the selectivity is generally the size of the component—particles or molecules larger

than the membrane pores are retained while the smaller ones pass through. Membrane operations cover a broad range of pore sizes. Microfiltration (MF) membranes have pore sizes ranging from 0.1 to 5  $\mu\text{m}$ , and are used for the separation of particles from dissolved species. Ultrafiltration (UF) membranes have pore sizes ranging from 1 to 100 nm, and are used in applications where the retention of large molecules such as proteins is important. Reverse osmosis (RO) membranes retain practically all solutes other than the solvent. Nanofiltration (NF) membranes have pores, which are between RO and UF. Pore size is used to characterize the retentive properties of MF membranes, while the size of the molecules that would be retained by the membrane, sometimes called nominal molecular weight cutoff (MWCO), is used to characterize UF, NF, and RO membranes.

Membrane operations are conducted either in a direct flow filtration (also called dead end) mode or in a tangential flow filtration (TFF) mode. Direct flow filtration is simple and easy to implement but has limited capacity for applications with high-solid mass. TFF is capable of processing large-solid masses but is more complex and capital intensive.

## 14.1.1 DIRECT FLOW FILTRATION

### 14.1.1.1 General Principles

In the pharmaceutical industry, most of the critical membrane filtration operations, such as sterile and virus filtration, are performed in the direct flow filtration mode where a feed solution passes directly through a membrane. As the solution passes through the membrane, particles are retained by size exclusion or adsorption. Direct flow filtration can be operated under constant flow or constant pressure modes.

The performance of direct flow filters can be characterized in terms of three parameters: flux, throughput, and retention. Flux is the filtration flow rate per unit area and follows D'Arcy's law [1]. It is proportional to the pressure driving force and inversely proportional to the hydraulic resistance of the porous media and the viscosity of the solution.

Throughput characterizes how much filtration can be conducted before the operation needs to be stopped due to fouling. As the membrane fouls there is a decrease in the flux or an increase in transmembrane pressure (TMP) depending on the operation mode, and the operation is stopped when either the flux is too low or the TMP is too high. The amount of filtrate that is processed per unit membrane area is called throughput.

Filter plugging can be caused by different dynamics [2–4]. Particles that are larger than the largest membrane pore are retained on the surface and form a cake. Particles of similar size to the size of the pores can completely block pores and reduce the effective surface area of the membrane. Particles that are smaller adsorb to the internal surface of the pores, reducing their effective diameter and increasing the hydraulic resistance of the media. In an actual filtration operation all these dynamics can work together in fouling the membrane [5]. The amount and type of fouling is strongly dependent on solution properties and operating parameters. The composition, particle size distribution, temperature, pH, and ionic strength of the feed solution can play an important role on the rate of fouling. Operating parameters such as the mode of the filtration operation, i.e., constant flow or constant pressure, and the selected pressure or flow rate are important as well.

Retention is a function of the pore size distribution of the membrane, solution properties, and operating conditions. For critical applications such as sterile or virus filtration, retention should be tested with the actual solution under different operating conditions. Typically, membrane filters are tested for integrity before use to ensure the required retention is obtained during operation. Integrity tests are based on bubble point or diffusion [6].

Direct flow filters are available typically in cartridge format, such as 10–40 in. (25–100 cm) lengths. Cartridges contain membranes that are pleated to provide the maximum amount of surface area within a single cartridge. Direct flow filters are also available as self-contained disposable capsules that do not require the use of housings. The ease of use associated with capsules has increased their use.

There are several categories of direct flow filtration; however, this chapter covers the three major ones—sterile filtration, virus filtration, and membrane adsorbers—as well as depth filtration.

### 14.1.1.2 Sterile Filtration

Sterile filtration is used in the biopharmaceutical industry to sterilize heat-labile products and to keep the bioburden low by filtering process intermediates and buffers. A sterilizing grade filter is defined as a filter that will produce a sterile filtrate when challenged with  $10^7$  colony-forming units of *Brevundimonas diminuta* [7]. The membranes used for sterile filtration can be based on various polymers such as nylon, PVDF, PES, and polypropylene. They can also have different structures such as isotropic or asymmetric. Asymmetric membranes have a graded pore structure that provides for high permeability while maintaining the required mechanical strength. These structures can also result in higher throughput due to particles being retained throughout the depth of the filter.

For sterile filtration, filterability and validation experiments are typically conducted at the laboratory scale to determine the size of the large-scale system and verify the absolute retention of bacteria with the actual process solution and operating conditions.

In a typical application, the filters are sterilized by autoclaving or steaming in place and flushed with water for injection or buffer before filtering the actual process solution. A postuse integrity test is performed after the product solution has been filtered to ensure that the required retention performance was obtained during the filtration process.

#### 14.1.1.3 Virus Filtration

Virus filtration allows for the transmission of the product molecule while retaining virus particles. The extent of virus removal depends on both the pore size distribution of the membrane and the size of the virus. As viruses differ in size, virus filters have been developed accordingly with different pore size ratings. Large virus filters are designed to remove larger viruses typically having lipid envelopes such as retroviruses. They have been labeled as 50 or 70 nm filters. Small virus filters target non-enveloped viruses such as human parvovirus B19 or *Hepatitis A virus*. They are typically rated as 20 or 15 nm.

Virus filtration membranes are made of various polymers such as hydrophilized PVDF, hydrophilized PES, and cellulose. They are available in pleated cartridge and hollow-fiber formats. At present almost all virus filtration applications are performed in the direct filtration mode.

#### 14.1.1.4 Membrane Adsorbers

Membrane adsorbers are made of microfiltration membranes with modified surfaces to attach an appropriate ligand such as ion exchange, affinity, and hydrophobic interaction [8,9]. They are not limited by the mass-transfer resistance associated with conventional chromatography, where large molecules need to diffuse within pores to reach the binding site and adsorb. The slow rate of diffusion within the pores limits the flow rates that can be used in standard chromatography. In membrane chromatography, the separation media has large convective pores that allow for the fast transport of the solute to the binding sites. This results in high-binding capacities at high-flow rates, enabling membrane adsorbers to be operated at high throughputs.

Membrane adsorbers are mostly used in flow-through applications where the contaminants bind to the membrane while the product molecule flows through. In applications where the product molecule is large, membrane chromatography presents significant advantages over beads in the bind-elute mode because the large size of these molecules results in low-binding capacities for beads. Membrane adsorbers with different base membranes such as 0.8  $\mu\text{m}$  hydrophilic PES or 3  $\mu\text{m}$  cross-linked cellulose are available.

#### 14.1.1.5 Depth Filtration

A major alternative to direct flow membrane filtration is depth filtration, in which particles are removed throughout the filtration matrix rather than just at the membrane surface, by various mechanisms such as size exclusion, electrostatic, and hydrophobic interactions. Depth filters are typically composed of a bed of cellulose or polypropylene fibers together with an inorganic filter aid such as diatomaceous earth and a binder to form a filter sheet. The filter aid imparts the matrix very high surface areas and plays an important role in increasing both retention and the capacity. Depth filters can also have an electrostatic charge usually associated with the binder polymer.

### 14.1.2 TANGENTIAL FLOW FILTRATION

#### 14.1.2.1 Fundamentals

Direct flow filtration has certain limitations. The flux (filtration flow rate per unit membrane area) decreases over time as the process continues because the filtering media is loaded with more contaminant particles, as illustrated in Figure 14.1. Moreover, when the concentration of the contaminant in the feed stream is high, the filtering media must be replaced very frequently, which can be economically impractical. Also when the contaminant matter to be separated is small in size, requiring ultrafiltration or reverse osmosis membranes with much smaller pores, then direct filtration is less feasible as the flux declines very rapidly over time, again requiring frequent filter replacement.

Tangential flow filtration technology, also known as crossflow filtration, overcomes these direct flow filtration limitations. TFF is a continuous process in which the feed stream flows parallel (tangential) to the membrane filtration surface, generating two ongoing streams. A part of the feed stream, which gets separated by passing through the membrane is called permeate or filtrate. The remaining portion of the feed stream, called retentate or concentrate, contains the components retained by the membrane [10].

TFF membranes can be cleaned or regenerated using chemicals (sodium hydroxide, acid, sodium hypochlorite, etc.) and mechanical methods (backwash, backpulse, reverse flow, etc.). Regenerated membranes can be used repeatedly, with effective lifetimes ranging from months to years. TFF module configurations and operating modes differ from direct filtration. Table 14.1 shows how TFF products are categorized according to membrane pore size or rating, membrane material, compatibility, shear generating method, etc. As a quick rule of thumb, TFF can be the optimal processing choice for those pharmaceutical

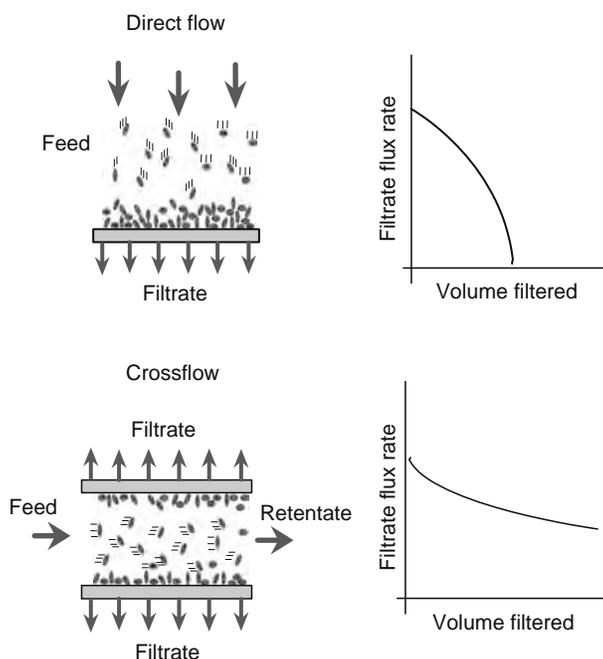

FIGURE 14.1 Direct flow and crossflow.

applications where (1) concentration of retained components is too high for direct flow; (2) concentrated material (retained by membrane) is a desired end product; and (3) diafiltration is required for desalting or buffer exchange or increased recovery.

#### 14.1.2.2 Effect of Polarization on Flux

During TFF, species retained by the membrane form a concentrated boundary layer, called concentration polarization layer, on the surface of the membrane that creates a resistance to the filtrate flow and reduces flux [11]. The effect of polarization is a flux—usually called limiting flux—that does not change with TMP above a critical pressure as shown in Figure 14.2.

#### 14.1.2.3 Processing Modes

TFF is widely applied in biopharmaceutical downstream processes including concentration, clarification, fractionation, and diafiltration.

1. Concentration is probably the most frequently used crossflow processing mode, in which molecules smaller than the membrane pore size rating pass through the membrane as permeate, with a net effect of increasing the concentration of retained components in the feed stream. During a concentration run, the flux decreases with increasing bulk concentration as illustrated in Figure 14.3. Typically, a pharmaceutical feed stream that starts out with a protein content of 1% can be concentrated up to 20% or more.
2. Clarification is another crossflow processing mode, often used as a preliminary step before the concentration operation, in those cases where the feed stream contains excess suspended solids or unwanted microorganisms, usually employing microfiltration membranes.

TABLE 14.1  
TFF Product Categories

Rating	MF/UF/NF/RO
Membrane material	Polymeric (PES, PS, R-CA, PVDF, etc.), inorganic (ceramic, stainless steel)
Configuration	Flat sheet (cassette, P&F, spiral), hollow fiber, tubular, monolith
Operating feature	Backwashable, backpulsable, steamable, autoclavable
Shear generation	Pump, mechanical
Pressure generation	Pressurize feed, vacuum filtrate

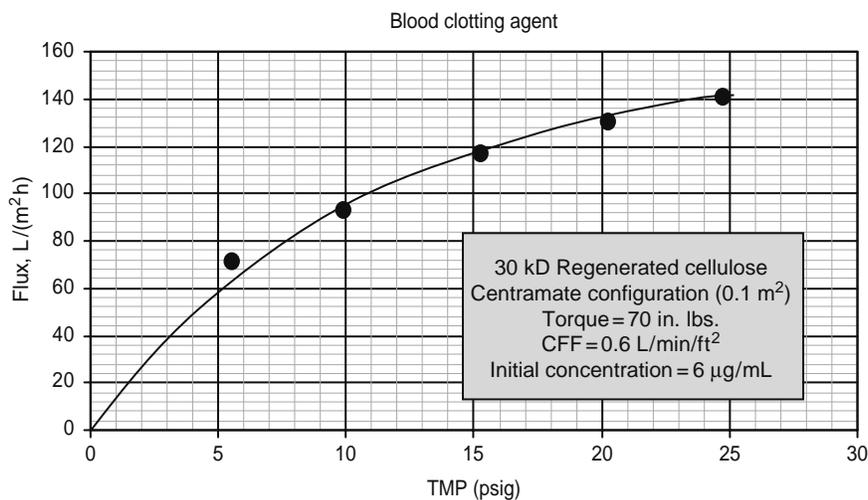

FIGURE 14.2 Flux versus TMP (transmembrane pressure) for a blood clotting agent.

3. Fractionation commonly refers to a process when both the concentrate and the permeate are valuable end products in their own right. The filtration of conjugated vaccine to separate oligosaccharides is a good example of fractionation by TFF in the biopharmaceutical industry.
4. Diafiltration (DF) is conducted by adding fresh solvent or buffer to the feed tank. The removal of salt from a feed solution by diafiltration is illustrated in Figure 14.4. There are several possible diafiltration modes depending upon system configuration and DF solvent/buffer flow direction, but continuous DF (also called constant volume diafiltration) mode is very typical and most often used.

#### 14.1.2.4 Membrane Module Configuration

Crossflow filtration membranes can be produced in flat sheet, hollow fiber, tubular formats when using polymeric materials, and in monolith and tubular configurations when using inorganic membrane materials. Table 14.2 summarizes the various module configurations.

*Cassette:* Cassette products are widely used in the biopharmaceutical industry and specifically dominate the protein concentration purification market due to their compactness, which provides excellent product recovery capability. Cassette modules contain presealed flat sheet membranes separated by feed and filtrate spacers. This is an improved design compared to earlier “plate and frame” configurations, making installation and replacement much easier and more reliable for the end user (shown in Figure 14.5).

Cassettes use a short feed channel path length to reduce the feed channel pressure drop. Flat sheet membranes used in cassettes allow for a wide ranging selection of MWCO in UF membranes, as well as various micrometer ratings in MF

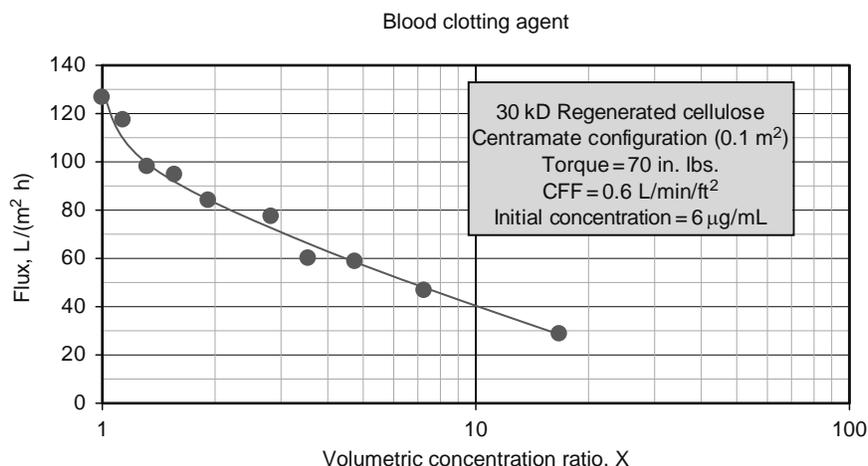

FIGURE 14.3 Flux versus feed concentration for a blood clotting agent.

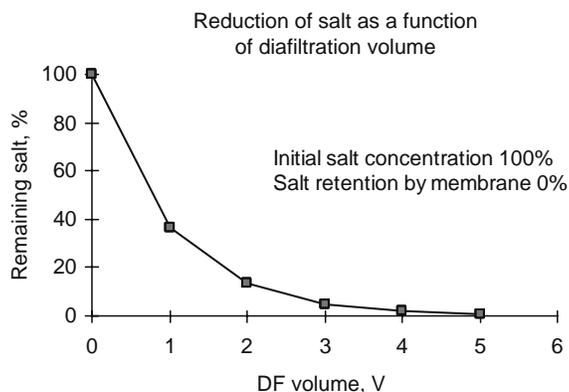

FIGURE 14.4 Salt reduction by diafiltration.

**TABLE 14.2**  
**Membrane/Module Configuration**

Membrane	Module	Feature	Major Application
Flat sheet	Cassette	Compact, high product recovery	Biotechnology, biopharmaceutical
	Spiral wound	Inexpensive	Food and beverage, industrial
	Plate and frame	Open channel	Food and beverage, industrial
Hollow fiber	Hollow fiber	No spacer, easy to replace	Biotechnology, biopharmaceutical, pharmaceutical water, makeup water
Tubular	Tubular	High solids	Food and beverage, industrial

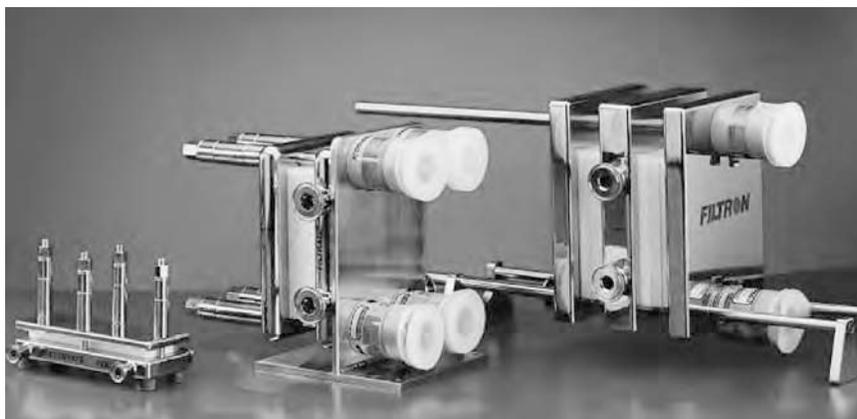

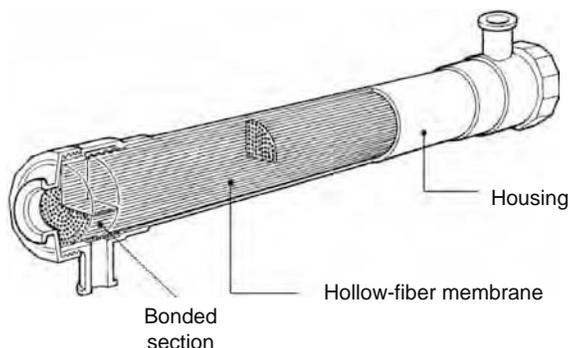

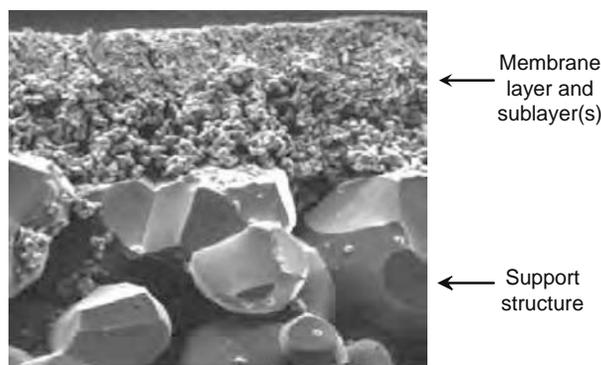

FIGURE 14.5 Cassette modules used in biotechnology applications.

Microza is a tradename of Asahi Kasei Corporation

FIGURE 14.6 Configuration of Microza hollow-fiber module.

**FIGURE 14.7** Structure of ceramic membrane.

membranes. This broad selection is critical for the successful processing of different protein sizes required in the pharmaceutical industry.

*Hollow Fiber:* Hollow-fibers are open channel products; however, due to their small fiber diameters, they do not require the high-energy consumption of tubular membrane products. Hollow fibers are self-supported; they do not require additional support substrates like flat sheet membranes do. Figure 14.6 shows a schematic of a hollow-fiber module.

Hollow fibers can be steamed, autoclaved, and are easy to replace, making them a frequent choice for continuous fermentation applications. They are frequently used for clarifying fermentation broths. Hollow fibers, typically with a 6000 Da MWCO, are also used in producing pharmaceutical grade (WFI) water.

*Ceramics:* Ceramic membranes are manufactured by processes, which are completely different from polymeric membranes. Polymeric membranes are typically formed by the phase inversion process where the polymer dissolved in solvent precipitates upon exposure to nonsolvent. In contrast, ceramic membranes consist of ceramic particles that have been sintered at very high temperatures into one solid shape. It is the gaps or voids between the solid-state ceramic particles that determine the membrane pore size (Figure 14.7).

Ceramic membranes are cast within feed channels, contained in support structures that are then inserted in housings. To reduce energy/flow requirements, up to two to four membrane housings can be connected in series.

Ceramic membranes are robust, easy to clean, and are available with large diameter feed channels, making them a strong technology for clarifying fermentation broths.

*Spiral Wound:* Spiral-wound membrane products are similar to cassettes since they combine flat sheet membranes and feed/permeate spacers, but the flat sheet membrane and the spacer pack are rolled or wound into a spiral form. Spiral-wound modules have much longer feed path lengths than cassettes.

*Vibrating Membrane:* The previously described TFF products require a pump to produce crossflow along the membrane surface to generate the shear rate necessary to reduce polarization and fouling. In contrast, in this configuration the membrane vibrates creating shear at its surface. This vibrating membrane arrangement, suitable for high concentration and viscosity processing, is used in antibiotics and enzyme applications.

## 14.2 MEMBRANE APPLICATIONS

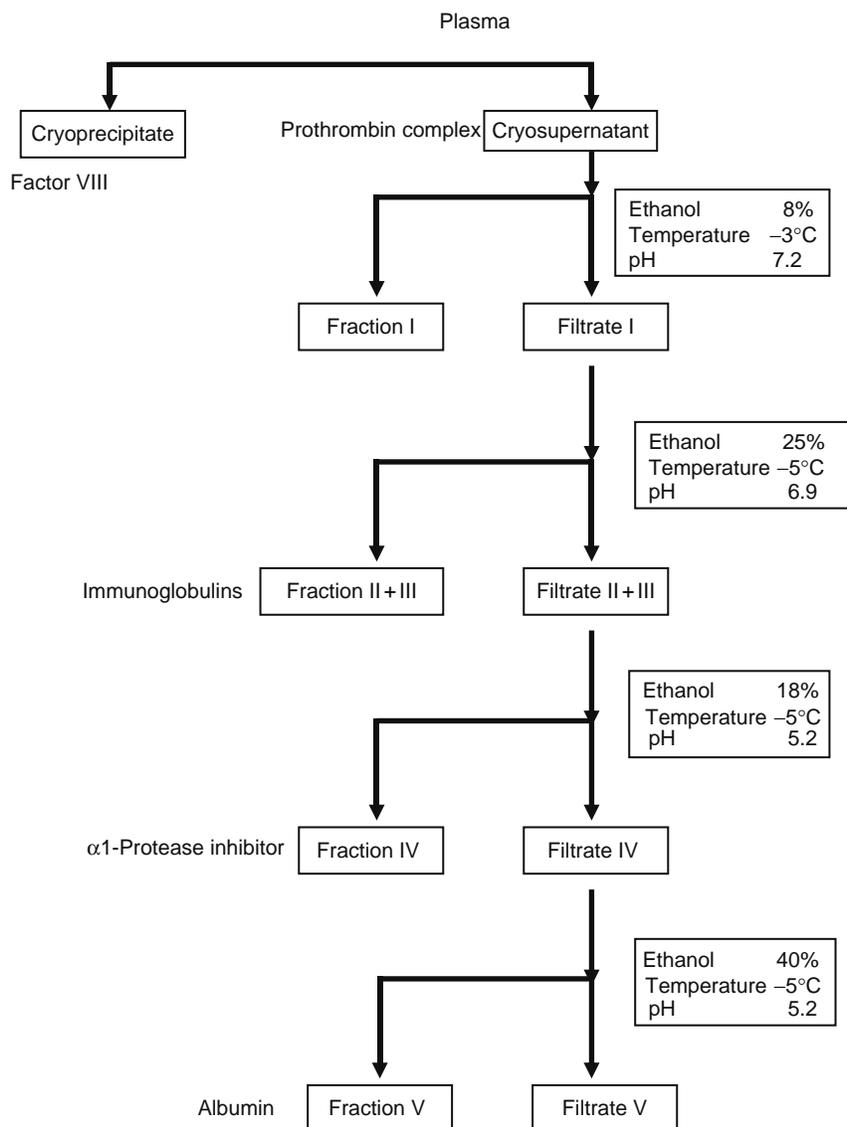

### 14.2.1 PLASMA FRACTIONATION

Human plasma provides the starting material for a large number of proteins (700 or more) that are of therapeutic relevance. These include albumin, immunoglobulins, blood clotting factors such as Factor VIII and Factor IX, and protease inhibitors. Under physiological conditions, plasma proteins have a broad range of concentrations, from 40 g/L for albumin to less than 1  $\mu\text{g}/\text{mL}$  for some clotting factors, and molecular weights (MWs). Some of the important plasma derivatives, their therapeutic use, and concentrations in the plasma are listed in Table 14.3.

The first purification process for plasma-derived products was specifically developed for the supply of albumin by Edwin Cohn during World War II. This process was based on a cold ethanol fractionation relying on the solubility of proteins changing as a function of ethanol concentration, pH, temperature, ionic strength, and protein concentration [12]. During fractionation, the ethanol concentration is raised from 0% to 40% and the pH decreased from neutral to 4.8 through different stages of sequential differential precipitation. A block diagram depicting the stages of Cohn fractionation is shown in Figure 14.8.

**TABLE 14.3**  
**Molecular Weights and Plasma Concentrations of Some Important Plasma Proteins**

Protein	Molecular Weight (Da)	Concentration in Plasma (mg/L)	Indication
Albumin	66,000	40,000	Volume replacement
Immunoglobulin G	160,000	12,500	Replacement therapy in immune deficiency
Von Willebrand factor	220,000	10	Von Willebrand's disease
Factor VIII	330,000	0.3	Hemophilia A
Factor II	72,000	150	Factor II deficiency
Factor VII	50,000	0.5	Factor VII deficiency
Factor IX	57,000	5	Hemophilia B
Factor X	59,000	10	Factor X deficiency
$\alpha$ -1-Protease inhibitor	54,000	1,500	Hereditary emphysema

**FIGURE 14.8** Cohn fractionation process (simplified illustration).

### 14.2.1.1 Factor VIII

Factor VIII is a high-molecular-weight protein (approximately 330 kDa) that is involved in blood coagulation cascades. The most important impurities that need to be removed during its purification process are fibrinogen and prothrombin complex (composed of Factors II, VII, IX, and X). The starting point for Factor VIII purification in most production processes is the cryoprecipitate that forms upon thawing frozen plasma at temperatures between 0°C and 4°C. Typically the cryoprecipitate is harvested by centrifugation, suspended in appropriate buffer, and filtered for the removal of fines. In addition, steps such as precipitation and chromatography are used to remove impurities. Virus inactivation/removal is obtained through multiple operations such as solvent/detergent treatment, dry heat treatment, and filtration. Ultrafiltration and diafiltration are performed at the downstream end of the process to concentrate Factor VIII to levels required for the final formulation, remove small-molecular-weight contaminants, and to obtain the desired buffer formulation. Sterile filtration is generally the last step before lyophilization. One of the important challenges in Factor VIII purification is the stability of the protein—it can lose its activity and precipitate easily.

### 14.2.1.2 Immunoglobulins

IgG is a 160 kDa protein that is administered intravenously or intramuscularly. The concentration of IgG for most intravenous formulations is 10% while it can go up to 18% for intramuscular formulations. The source material for IgG in most production processes is Cohn fraction II + III [13,14]. The paste is generally collected by centrifugation and suspended in water for injection. The solution is then clarified through depth filtration and purified by a series of precipitation steps where ethanol, caprylic acid or PEG are used as precipitating agents. Virus inactivation/removal is conducted through solvent/detergent treatment, heat treatment, and membrane filtration. One or more ion-exchange chromatography steps are used to further remove protein impurities and reagents used during solvent/detergent treatment. Ultrafiltration is used to remove precipitating agents and virus-inactivating reagents and to concentrate IgG to the levels desired for the final formulation. The last step in the purification process is sterile filtration.

### 14.2.1.3 Albumin

Albumin is a single-chain protein of 66 kDa molecular weight. It is supplied in concentrations of 5%, 20%, and 25%. The starting material for a typical production process is fraction V [15]. The paste is suspended in water and further purified through precipitation with ethanol. Depth filtration is performed to clarify the supernatant resulting from the precipitation steps. The purity of albumin is increased through polishing ion-exchange chromatography step. Ultrafiltration is used to concentrate albumin, remove ethanol, and provide the final formulation. The last step of the purification process is sterile filtration.

### 14.2.1.4 $\alpha$ -1-Protease Inhibitor

$\alpha$ -1-Protease inhibitor is a 52 kDa protein that protects lungs against proteolytic damage caused by elastase. The source for  $\alpha$ -1-protease inhibitor is Cohn fraction IV-1 [16]. The paste is dissolved in appropriate buffer and subjected to precipitation and chromatography operations for purification. Virus inactivation is provided by solvent/detergent and heat treatments. Ultrafiltration and diafiltration are performed in between chromatography steps to obtain the buffer environment necessary for the subsequent chromatography step. The last step of the purification process is sterile filtration.

### 14.2.1.5 Prothrombin Complex

Prothrombin complex is the combination of Factors II, VII, IX, and X. It is indicated for individuals with hemophilia B. In a typical production process, the supernatant resulting from the separation of cryoprecipitate is filtered to remove particles and applied to an anion-exchange column. The coagulation factors are eluted, ultrafiltered, and exposed to 60°C for 10 h for virus inactivation. This is followed by diafiltration, ultrafiltration, and sterile filtration.

### 14.2.1.6 Membrane Operations during Plasma Fractionation

Filtration plays an essential role during plasma fractionation. Practically all plasma derivatives are processed with sterile filtration at the end of the purification train. Virus filtration is becoming a very important part of viral safety management and it is being incorporated to most processes. Ultrafiltration and diafiltration are used in all processes to remove reagents such as ethanol and salt, concentrate the protein to the desired level, and exchange the buffer to the appropriate conditions before a chromatography operation. Finally, each precipitation step is accompanied with clarification filtration to remove residual precipitates. Below is a more detailed discussion of the various filtration operations.

#### 14.2.1.6.1 Sterile Filtration

Sterile filtration during the production of plasma derivatives is performed to sterilize product intermediates, final product, and buffers. Typically filtration fluxes of 200–1000 Lmh are obtained depending on the solution. Typical operating pressures are within the range of 5–20 psi. In cases of solutions with high protein concentrations or containing aggregates, sterile filtration

can be challenging. For example for IgG and albumin processing where the concentration of the proteins is high (up to 25% for albumin and to 12% for IgG) and the processing temperatures are low, the solutions can be viscous and difficult to filter. Generally, immunoglobulins and Factor VIII are slower to filter than albumin [17].

The presence of colloids in the solutions necessitates pre-filtration to increase the capacity of sterile filters. Usually a filter train of increasingly tighter filters such as 1, 0.45, and 0.22  $\mu\text{m}$  (or 0.65, 0.45, and 0.22  $\mu\text{m}$ ) is used to limit clogging. The sequence of filters and their surface areas in the filter train should be optimized by experiments. In certain cases, depth filters are used to protect sterile filters.

Some large proteins such as fibrinogen or Factor VIII can demonstrate retention by the sterilizing grade filters. The effect of solution properties such as pH, ionic strength, temperature, and operation parameters such as TMP on retention should be understood to minimize the loss of the product protein.

Sterilizing grade filters are available from various suppliers such as Pall Corporation (East Hills, New York), Sartorius AG (Göttingen, Germany), and Millipore Corporation (Billerica, Massachusetts). A typical filtration operation consists of the sterilization of the filters by autoclaving or SIP, flushing the filter with WFI, preuse integrity testing, buffer conditioning, filtering the protein solution, and postuse integrity testing. The filtration of the solution is usually conducted under constant TMP of 5–20 psi. TMP can be increased as the filtration rates decline due to fouling.

#### 14.2.1.6.2 Clarification/Prefiltration

Depth filters are typically used to clarify the paste suspended in WFI or the supernatant from the precipitation step. In many cases, the filtrate from the depth filter is further clarified with a 0.45  $\mu\text{m}$  membrane.

The capacity of expensive sterile and virus filters is usually increased through prefiltration. Typically 0.1  $\mu\text{m}$ -rated membranes are used for prefiltration before virus filtration. Sterile filters are protected by depth filters or 0.45  $\mu\text{m}$  membranes. Some virus inactivation operations such as solvent detergent exposure also require prefiltration for the removal of particulates that can shield viruses from the inactivating effects of solvent detergent agents.

#### 14.2.1.6.3 Virus Filtration

Virus filtration is one of the critical steps in the production of plasma derivatives as outbreaks of hepatitis A, hepatitis C, and HIV in hemophiliac populations have underlined the importance of virus inactivation/clearance during these processes [18]. The concerns about the safety of plasma derivatives are managed by a multilayer approach. As a first step, donors are screened through blood tests, interviews, and review of their medical history. In addition to that the collected plasma is tested for infectious agents, and manufacturing processes have multiple virus inactivation/removal steps with sufficient viral clearance. It is recommended that production processes have at least two virus removal/inactivation steps complementary in their mode of actions. Viral inactivation methods that are commonly used are precipitation, solvent/detergent treatment, pasteurization at 60°C for 10 h, caprylate treatment, and low-pH treatment. Among these methods, solvent/detergent, low-pH, and caprylate treatments are not effective against nonenveloped viruses.

Viruses that contaminate human plasma range from 20 to 200 nm in size, with a majority containing lipid envelopes and a few, such as HAV and B19, being nonenveloped. The difficulties associated with the inactivation of nonenveloped viruses with methods such as solvent/detergent or low-pH exposure makes the clearance of such viruses with filtration important. Virus filters with mean pore sizes of 20 or 15 nm are used for such applications. While this type of filtration is relatively easy for cases where the product protein is small, such as Factor IX, when the size of the product protein is large, the process becomes much more difficult due to the relatively small size difference between the virus and the protein. In these cases the filtration conditions need to be optimized to obtain acceptable viral clearances without compromising from the protein yield. Virus filtration for Factor VIII has mostly been conducted with 35 or 50 nm filters because of the large size of Factor VIII. Certain manufacturers have been successful in using smaller diameter filters without losing significant yield, by dissociating Factor VIII from Von Willebrand Factor. In other cases, the optimization of the filtration conditions has resulted in the acceptable use of 20 nm virus filters for processing Factor VIII [19]. Virus filtration for IgG products has in general been conducted with 35 to 50 nm filters. There have recently been reports of success with the use of 15–18 nm filters for processing IgG [20].

Virus filtration operations typically need prefiltration due to the presence of aggregates that shorten the capacity of the filter. Prefilters with pore sizes of 0.1  $\mu\text{m}$  or 75 nm have been used. In certain cases, the fouling of the filter and the accompanying flux decline result in the degradation of viral retention.

Virus filters are available from various suppliers such as Pall Corporation (East Hills, New York), Sartorius AG (Göttingen, Germany), Asahi Kasei Pharma Corporation (Tokyo, Japan), and Millipore Corporation (Billerica, Massachusetts). A typical virus filtration operation consists of sanitizing or sterilizing the filter, flushing the filter with WFI, preuse integrity testing, filtering the solution, and postuse integrity testing. In most applications the filtration is conducted in the constant TMP mode, at a typical TMP of 10–30 psi. Typical fluxes are in the range of 10–50 L m h.

#### 14.2.1.6.4 Ultrafiltration

Ultrafiltration is conducted to remove precipitating agents such as ethanol, PEG, and caprylic acid through diafiltration and to concentrate the protein to the desired level. It has replaced lyophilization for ethanol removal from albumin and immunoglobulins and size exclusion chromatography for buffer exchange.

The processing of plasma derivatives with ultrafiltration is usually conducted in cold rooms. For albumin processing, cassettes and spirals with 10 kDa polysulfone and polyethersulfone membranes have been used to remove the 40% ethanol as quickly as possible and for concentrating the protein to the final concentration of 25%. Typically, 4–5 diafiltration volumes are used to remove ethanol. For high concentration HSA formulations (25%), the protein is first concentrated to 12%, diafiltration conducted under constant volume conditions at that concentration and the protein subsequently concentrated to 25% [21,22]. Typical fluxes for albumin range between 50 and 100 Lmh with operating TMPs ranging between 30 and 50 psi.

Typically 30 or 50 kDa membranes are used for concentrating and diafiltering immunoglobulins. Diafiltration is generally conducted at IgG concentrations of 7%–8%. Typical fluxes are 25–70 L m h with typical operating TMPs ranging between 20 and 40 psi. For high concentration formulations, the viscosity of the solution increases as IgG is concentrated resulting in high-pressure drops in the feed channel. The user may need to reduce the crossflow rate to keep the pressure drop within specifications. The formation of IgG aggregates during the ultrafiltration operation needs to be minimized by determining the effect of operating and solution conditions on aggregate formation [23].

The processing of Factor VIII is usually conducted under low crossflow rates to avoid any loss in activity.

Ultrafiltration modules are available from various suppliers such as Pall Corporation (East Hills, New York), Sartorius AG (Göttingen, Germany), GE Healthcare (Buckinghamshire, England), and Millipore Corporation (Billerica, Massachusetts). A typical operation consists of WFI flush, water permeability testing, integrity testing, buffer conditioning, protein processing, buffer flush, water permeability testing, and cleaning.

### 14.2.2 ENZYMES AND ANTIBIOTICS

Today, many therapeutics including antibiotics, pharmaceutical enzymes, vaccines, and recombinant proteins are produced through fermentation or cell culture. Table 14.4 lists examples for some of these pharmaceuticals. While the use of fermentation can be traced back over 1000 years, it was following the discovery of penicillin in 1928 and its mass production by fermentation in the 1940s, that a wide range of antibiotics and other pharmaceuticals have come to be produced using large-scale fermentation processes [24]. Today, cephalosporin and penicillin V and G are among the antibiotics with the largest scale production. For some of the so-called semisynthetic antibiotics, fermentation is used to produce an intermediate product, which is then subjected to chemical reactions to produce the final product. Penicillin G and V (especially G) are more likely to be used as a raw material to produce an intermediate product such as 6-APA and 7-ADCA rather than as a final product. 6-APA is made by enzyme modification using penicillin acylase. The intermediate products are then converted to final products such as amoxicillin, ampicillin, and carbenicillin. Fermentation, plus a synthetic modification method, is also used in the manufacture of semisynthetic cephalosporin products.

Enzymes are typically produced using fermentation. They cover a wide variety of applications (see Table 14.5) including their use in the production of antibiotics (as noted above with the use of penicillin acylases to produce 6-APA from penicillin).

Pharmaceutical production processes based on fermentation can be separated into two segments. Upstream processing consists of all the operations that are involved in producing the desired amount of target molecule in fermenters. Downstream processing encompasses all the separation and purification operations that are needed to obtain the required purity for the target molecule. In general, upstream processing consists of media preparation, and fermentation; while downstream processing includes cell separation, clarification, primary isolation, purification, depyrogenation, and final isolation. The objectives and technologies that are used are summarized in Figure 14.9 (although the exact steps will vary for each specific product). We provide more detail on upstream and downstream processing in the sections that follow.

---

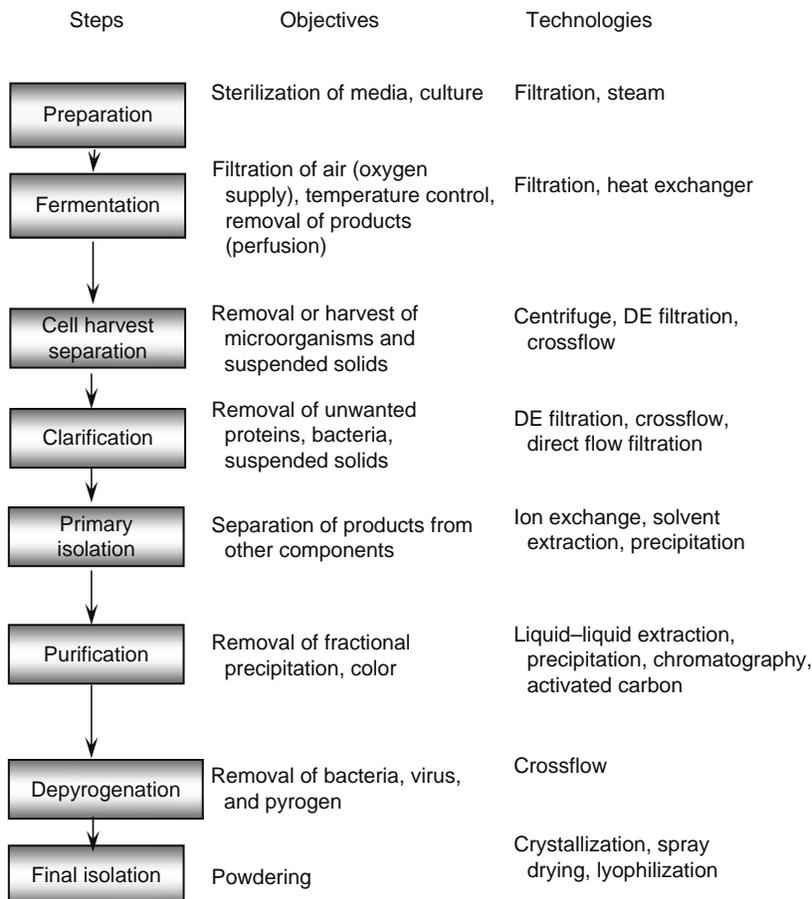

**TABLE 14.4**  
**Pharmaceutical Products by Fermentation and Cell Culture**

Antibiotics	Penicillin, erythromycin, cephalosporin, streptomycin, vancomycin, bacitracin, etc.
Enzymes	Amylase, protease, penicillinase, asparaginase, etc.
Recombinant proteins	TPA, protein A, hemoglobin, BMP, human growth hormone, IL2, antibodies
Vaccines	Influenza, hepatitis, DPT, cholera, <i>Streptococcus pneumonia</i>
Vitamins	B <sub>2</sub> (riboflavin), B <sub>6</sub> , B <sub>12</sub> (cyanocobalamin), C (L-ascorbic acid), β-carotene (provitamin A)
Steroids hormones	Cortisone, cortisol, prednisone
Nucleic acids	ATP, IMP, GMP, cAMP, adenine, inosine, etc.

---

**TABLE 14.5**  
**Enzymes for Pharmaceutical Application**

Enzyme	Producing Organism	Application
Amylase	<i>Aspergillus</i> , <i>Rhizopus</i> (mold), <i>Bacillus subtilis</i> (bacteria)	Digestive agent
Asparaginase	<i>Escherichia coli</i> , <i>Serratia marcescens</i>	Leukemia
Lactase	<i>Saccharomyces fragilis</i> (yeast)	Digestive agent
Lipase	<i>Aspergillus niger</i>	Digestive agent
Penicillinase	<i>Bacillus cereus</i> , <i>B. subtilis</i>	Benzyloxyphenylacetic acid production
Penicillin acylase	<i>E. coli</i> , <i>Kluyvera citrophila</i>	6-APA production
Protease	<i>Bacillus subtilis</i> , <i>Clostridium</i> , <i>Lactobacillus</i> (bacteria), <i>Streptomyces griseus</i> (mold)	Digestive agent, blood clotting effect
Urokinase	<i>E. coli</i> , animal cell	Thrombolytic agent, plasminogen activation
Streptokinase		Thrombolytic agent
Lysozyme		Anti-inflammation
Elastase		High-blood pressure, diabetes, arteriosclerosis
Cytochrome		Improves oxygen consumption for strokes, etc.
<b>Diagnosis</b>		
Uricase	<i>Candida utilis</i> , <i>E. coli</i>	Uric acid
Glucose oxidase	<i>A. niger</i> , <i>Penicillium chrysogenum</i>	Glucose
Cholesterol oxidase	<i>Brevibacterium sterolicum</i>	Cholesterol
Lipase	<i>A. niger</i>	Triglyceride

**FIGURE 14.9** Fermentation process.

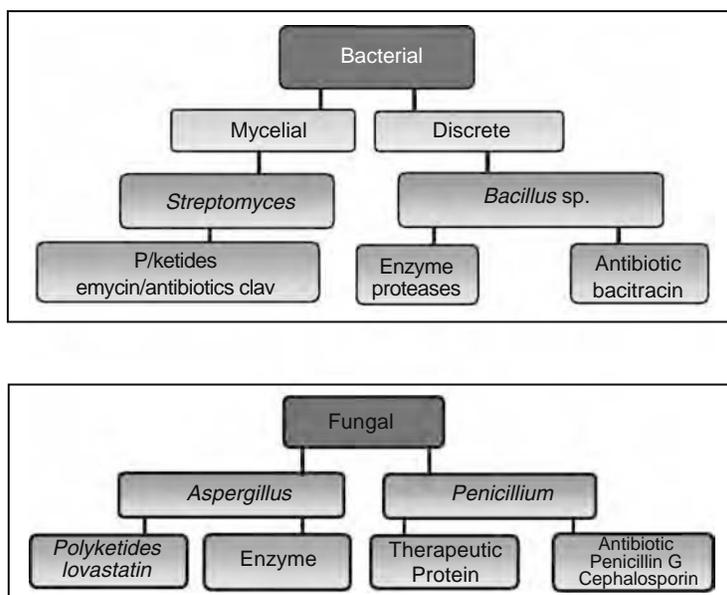

FIGURE 14.10 Large-scale fermentation for antibiotics etc.

### 14.2.2.1 Upstream Processing

Fermentation has been used to produce beer, wine, and other products for thousands of years. At the core of these processes lies the conversion of one component into another by microorganisms; for example the transformation of sugar into alcohol by yeast. For recombinant processes, the transforming microorganisms are modified using plasmids to insert gene sequences coding for the product of interest, along with promoters, etc.

The most commonly used microorganisms for fermentation are bacteria, fungi (mold), and yeasts whereas animal (mammalian and insect) cells and plant cells are used for cell culture (Figure 14.10). If the desired product is contained within the microorganism, it is referred to as intracellular, if outside it is extracellular. Bacteria, which typically produce intracellular products, are 0.2–2  $\mu\text{m}$  in size and can grow to more than  $10^9$  cells/mL. Yeasts are larger (3–4  $\mu\text{m}$ ) and grow to concentrations of over  $10^8$  cells/mL. They generally produce extracellular products. The generation times of bacteria, yeasts, and mammalian cells are 20–30 min, 3–4 h, and 1 day, respectively. In the case of optimized *E. coli* processes, for example 1 cell/mL can grow to  $10^9$  cells/mL after only 10 h.

Most of fermentation and cell culture operations are done in the batch mode where a volume of sterile medium in a vessel is inoculated, the broth is fermented for a period, and the contents of the tank are removed and filtered. Semi-batch or fed-batch modes can also be used during large-scale production processes. Continuous fermentation, where sterile medium is continuously added to the fermentation system with a balancing withdrawal of broth for the extraction of the target molecule, has only been applied to a limited number of products such as those produced with yeast. Such limited application is due to difficulties of maintaining sterility for a long period. However, the implementation of continuous fermentation in the production of antibiotics, amino acids, and nucleic acids is anticipated soon.

Fermentation processes need several components as starting materials: an inoculum, growth medium (carbon source such as carbohydrates and sugars, and nitrogen source such as ammonium salts), air/gas, and water. To have a successful fermentation, all these components have to be maintained as sterile to avoid contamination.

The culture media used in fermentation processes contains a variety of unwanted cells and spores which need to be inactivated or removed before fermentation. The most commonly used inactivation method is heat sterilization. Most cells and some spores can be destroyed at 60°C–80°C, while some heat-resistant spores such as bacterial spores require more than 120°C. Heat-based methods, however, cannot be used when the product molecules, such as vitamins and antibiotics, are heat sensitive, because the application of high temperatures changes their properties. In these cases, sterile filtration with membrane filters or depth filters is used.

During aerobic fermentation, used in the majority of pharmaceutical processes, air has to be supplied as the oxygen source. This leads to processing requirements since air contains as many as  $10^5$  particles/ $\text{m}^3$  and  $10^4$  cells/ $\text{m}^3$  of microorganisms, such as spores and bacteria. Traditional technologies used include heat, glass-packed towers, HEPA filters, and UV. However, these have now been replaced by much more reliable sterile filtration using 0.2 or 0.1  $\mu\text{m}$  filters. Air/gas has to be filtered not only when incoming into the fermenter but also outgoing from the fermenter to avoid any microbial contamination. In many cases, enriched oxygen air or pure oxygen is used to increase the mass transfer of oxygen and to allow for higher cell density and

productivity. Higher oxygen concentration poses a challenge when selecting the material for filter media and its components. PTFE membranes, antioxidant components, and special configurations are used to deal with the corrosion problem as well as the issue of fire hazards.

### 14.2.2.2 Downstream Processing

#### 14.2.2.2.1 Clarification

The first step following fermentation is the separation of solids from the liquid growth media, a step generally referred to as cell separation. More specifically, when the desired products are contained within the cells (intracellular) this step is called cell harvesting and when the products are extracellular it is known as broth clarification. The list of antibiotics with their producer organisms, molecular weight, and whether they are extracellular or intracellular is shown in Table 14.6.

To accomplish this separation step, centrifugation has traditionally been used and is still used for many applications. However, centrifugation has some limitations. Most importantly, it does not achieve the required clarity and therefore, typically leads to further downstream clarification requirements—depth filtration is the most common operation applied to centrate in such cases.

As an alternative to centrifugation, a vibrating membrane filter is used in some applications such as yeast processes (*Pichia pastoris*) and vaccine processes. Diatomaceous earth (DE) filtration is another potential alternative. Figure 14.11 illustrates DE embedded within a filter module structure.

Ceramic membrane systems are achieving widespread application in the place of centrifuges. These systems do not require filter aid media or a separate follow-on clarification step. Hollow-fiber crossflow modules are preferred for the separation of mammalian cells, which require particularly gentle handling. They can also be used as disposable filters for perfusion and vaccine processes.

When clarifying antibiotics there are some specific considerations to keep in mind; most important is whether or not the product is intra or extracellular. Penicillin V, G, and many others are extracellular products. In such cases, the target antibiotics are excreted into the broth. For clarification, a crossflow system with ceramic membranes or hollow fibers is therefore widely used. The permeate (filtrate) contains the desired product. Diafiltration can also be used to improve upon the yield.

If the desired product is intracellular, cells are first concentrated and then lysed to release the product. Extraction by solvent or pH change is used alone or in conjunction with the mechanical disruption. The resulting lysate is then clarified to remove cell debris leaving only the clarified products. With the introduction of ceramic membrane systems, concentration, extraction, and clarification can be done using a single system. One example of an intracellular process, i.e., vitamin B<sub>12</sub> production (185 m<sup>3</sup> broth) is shown in Figure 14.12.

#### 14.2.2.2.2 Purification

The most common operations used for the purification of antibiotics and enzymes are extraction, crystallization, carbon adsorption, chromatography, and filtration. Antibiotics pose some particular challenges because they are small and likely to be purified using solvents. Therefore, purification is often undertaken using solvent extraction as in the case of Penicillin. Cephalosporin uses an ion-exchange resin as the primary isolation method. Enzymes processes use similar technologies but pose some distinct requirements because they are typically large and are produced in aqueous environments. They are therefore more likely to be purified using precipitation, chromatography, and ultrafiltration.

**TABLE 14.6**  
**Typical Antibiotics and Organisms**

Antibiotic	Producer Organism	Molecular Weight	Extra or Intracellular	
Bacitracin	<i>Bacillus subtilis</i>	1391	Extracellular	Intracellular
Cephalosporin	<i>Cephalosporium acremonium</i>	415	Extracellular	
Erythromycin	<i>Streptomyces erythreus</i>	734	Extracellular	
Griseofulvin	<i>Penicillium griseofulvum</i>	353		Intracellular
Neomycin	<i>Streptomyces fradiae</i>	322	Extracellular	
Penicillin	<i>Penicillium chrysogenum</i>	334, 350	Extracellular	
Semduramycin		895		Intracellular
Streptomycin	<i>Streptomyces griseus</i>	582	Extracellular	
Tetracycline	<i>Streptomyces rimosus</i>	444	Extracellular	Intracellular
Vancomycin	<i>Streptomyces orientalis</i>	407	Extracellular

### 14.2.3 ACTIVE PHARMACEUTICAL INGREDIENTS

Most active pharmaceutical ingredients are produced by synthesis through a series of chemical reactions where different functional groups are attached to the starting raw material. In some cases, the production involves a semisynthetic process where the starting material originates from the extraction of a substance from a botanical or animal source or from fermentation.

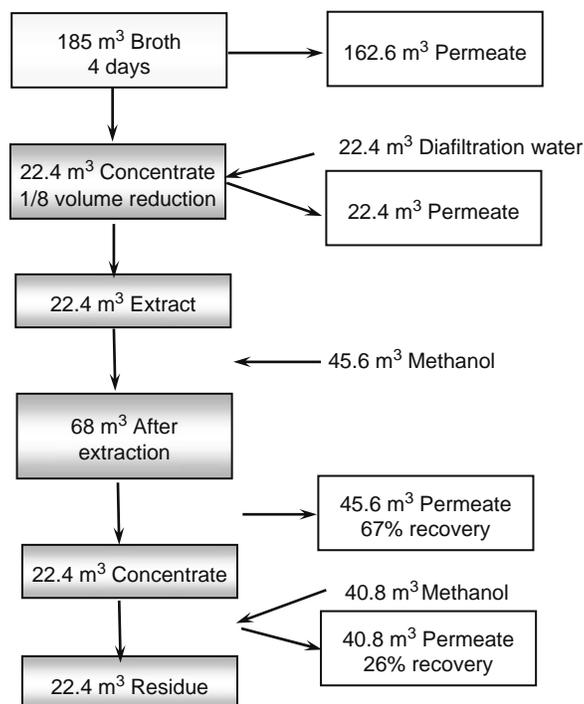

FIGURE 14.12 Clarification/extracton process for vitamin B<sub>12</sub> production.

The products formed after each stage of reaction are termed as intermediates. Some type of isolation operation such as extraction, filtration, or distillation is usually conducted on the reaction mixture at each intermediate step. The final reaction mixture goes through a series of purification operations such as precipitation, distillation, chromatography, filtration, and crystallization where impurities are removed. These impurities can include residual-unreacted starting materials, by-products of reactions, catalysts, residual solvents, and enantiomeric forms of a chiral drug. The last step of the process is usually crystallization where the active product is recovered in the desired morphological form. The crystallized product is typically recovered by filtering, washing, and drying.

Various types of reactions including halogenation, alkylation, arylation, oxidation, reduction, sulfonation, esterification, and amination are used in the production of active pharmaceutical ingredients. These reactions typically take place at high temperatures in stainless steel or glass reactors of various sizes ranging from 50 gal at the pilot scale to 3000 gal at the manufacturing scale and require the use of catalysts and large volumes of solvents. As solvents are pumped from tank farms to the reactors, they need to be filtered to remove any particulate that could interfere with the reaction. For solvents with low solid concentrations polymeric cartridge filters are typically used.

The most important consideration in the selection of the filter is the compatibility of the filter materials of construction with the solvent. The solvents used in pharmaceutical processes can be very aggressive. They include acetone, methanol, ethanol, isopropyl alcohol (IPA), acetonitrile, dimethyl acetamide, dimethyl formamide (DMF), ethyl acetate, tetrahydrofuran (THF), methyl isobutyl ketone (MIBK), and methyl ethyl ketone (MEK). Filters with PTFE membranes and polypropylene supports are used in most applications.

Heterogeneous catalysts made of transition metals on various supports such as carbon are used in many reactions. At the completion of the reaction, the catalyst needs to be removed from the product mixture and recycled. The recovery of the catalysts can be conducted by centrifugal discharge or by using Nutsche-type filters. These types of filters retain large masses of solids and have the capability of washing and drying them. The filtrate is usually filtered through a solvent compatible cartridge to remove any fines that may still be in the liquid. The removal of homogeneous catalysts from the active pharmaceutical ingredient is more difficult. Distillation, adsorption, and extraction have been used. Recently, solvent-resistant nanofiltration devices have been targeted for this application. The filtrate containing the intermediate product can be further purified by activated carbon for clarification. The use of sheets impregnated with carbon simplifies the operation over the batch process by eliminating the carbon removal step.

The gasses going to the reactors, such as nitrogen that is used to blanket the reactor and hydrogen that is used as a reactant, are filtered with gas filters typically made out of PTFE membranes. Since the filters can be exposed to the solvents used in the reactors the materials used in their construction need to be compatible with the solvents.

Usually the type of solvent that is optimum for a particular reaction or purification step is different from what would be optimum for a different step. Therefore, solvents are changed several times during the process. This exchange can be conducted by precipitation and evaporation followed by dissolution in the new solvent. Solvent-resistant nanofiltration can also be used for solvent exchange during the process. Typically the used solvent is purified by distillation and recycled. The product mixture from the last reaction step is typically purified by crystallization, washing, and drying.

#### 14.2.4 PARENTERALS

Parenteral solutions are typically administered intravenously. They are packaged as large volume parenteral (LVP) and small volume parenteral (SVP) solutions. LVP solutions are bags or bottles containing from 100 mL to 1 L solutions. They are usually administered for electrolyte and fluid balance disturbances, nutrition and as a vehicle to administer other drugs. The most common examples of LVPs are sodium chloride, Ringer's, sodium bicarbonate, dextrose, amino acids, dextrans, and other plasma expanders. Due to the large volumes involved, LVPs should not contain bacteriostatic agents, or other additives and excipients. SVPs are 100 mL or less and their primary use is the delivery of a medicine. They can be packaged as 50–100 mL bags, ampules, vials, and prefilled syringes. SVPs can have antibacterial preservatives, solubilizers, antioxidants, and other excipients.

Parenterals are prepared under a controlled environment by dissolving the drug and excipients in water for injection, and sterilizing the bulk solution by passing it through a sterilizing grade filter, filling individual sterile containers. The air to the production facility is filtered by HEPA filters.

The water used for preparing parenteral solutions needs to meet USP requirements for water for injection. These requirements include bacterial endotoxins no greater than 0.25 eu/mL, total organic content less than 500 ppb, and a conductivity of 1.3  $\mu\text{S}/\text{cm}$ . Water for injection is prepared by distillation or a two-stage reverse osmosis process. A typical process to produce water for injection consists of multimedia filtration, softener, activated carbon, 1–5  $\mu\text{m}$  prefiltration, UV treatment, two-stage reverse osmosis, mixed DI, UV, and sterile filtration.

### 14.3 FUTURE TRENDS

Membrane separation applications with higher selectivity, capacity, and flow rates are driven by the need for more economical and robust manufacturing processes providing higher purity products. In the area of virus and sterile filtration, membrane providers are developing high capacity and high-flux membranes by the use of multilayer structures. New module designs are packing more membrane material within the same module volume. Advances in processing are yielding membranes with lower levels of extractables. For TFF, better fluid management technologies will result in processes more resistant to fouling [25]. Advances in module design, membrane chemistry, and application knowledge are resulting in membrane applications with high-purification factors [26]. Disposable TFF devices will eliminate the complexity of TFF systems and eliminate cleaning validation. The use of membrane adsorbers will simplify the purification operations in plasma and enzyme processing. Finally, solvent-resistant nanofiltration will make solvent exchange and catalyst recovery more economical and robust [27].

### 14.4 CONCLUSION

Membranes play an ever growing essential role in the economic manufacture of a multitude of pharmaceutical products. The membranes range from microfiltration and ultrafiltration to reverse osmosis and nanofiltration. Direct flow and crossflow membrane systems are used not only to concentrate, clarify, and diafilter the products themselves but also to pretreat the water needed during the manufacturing process, as well as to post-treat ensuing wastewaters. As membrane technology advances and as materials of construction improve, the process of applying membranes in the pharmaceutical world will expand. Benefits will include new products, lower manufacturing costs, improvements in purity, and rendering the production processes more environmentally friendly.

## 15.1 INTRODUCTION

A membrane can be defined as a sheet of solid or semisolid material, insoluble in its surrounding medium, which separates phases that are usually (but not necessarily) fluid [ 1]. A transport system is realized when there is a passage of solute across the membrane.

Based on mechanisms ruling mass transport, typically, membranes can be divided into two main classes: biological and synthetic membranes. Indeed, in synthetic membranes mass transport is usually only due to a chemical potential gradient, while in biological membranes mass transport can also be due to other special mechanisms. Facilitated diffusion implies solute binding to a protein embedded in the biological membrane and, then, protein–solute complex permeation through the membrane (this mechanism does not require energy as solute diffusion takes place according to the chemical potential gradient). Important examples are represented by  $H^+$ /organic cation antiport system and the dipeptide transporter [2]. Active transport denotes carrier transport processes consuming energy since transport often takes place against a chemical potential gradient. The energy required for active transport can be supplied by two different mechanisms: cotransport and ATP pump [3]. In cotransport, the target molecule associates to another compound that crosses the cellular membrane due to the existing

concentration gradient (this is the case of glucose and aminoacids that associate to  $\text{Na}^+$  crossing the cellular membrane according to the concentration gradient). Instead, in the ATP pump case, the energy required for molecules transport is supplied by the hydrolysis of high-energy compounds such as ATP ( $\text{ATP} \Rightarrow \text{ADP} + \text{P} + \text{energy}$ ). A typical example is represented by the  $\text{Na}^+ - \text{K}^+$  pump. Finally, very large molecules are transported by invagination of the membrane and subsequent vesiculation and devesiculation (endocytosis or transcytosis).

While in biological membranes the above-mentioned phenomena can highly influence solute permeability, in synthetic membranes permeability is essentially due to solute chemical-physical properties and membrane microscopic structure. Indeed, synthetic membranes are usually complex structures that can be, in the most general case, composed of three different phases: (a) continuous, (b) shunt, and (c) dispersed [1]. These phase types may be further classified as primary, secondary, and tertiary, the subclassification depending on the spatial relationships of each phase to the other phases present. A primary continuous phase is an uninterrupted phase between membrane surfaces as well as laterally or in the plane perpendicular to the flux vector. Depending on its composition relative to the compositions of associated phases, it may provide an uninterrupted diffusional path for a solute or it represents an un-accessible zone acting as a mere supporting structure. A primary shunt phase completely passes through the membrane but it is laterally discontinuous, i.e., a pore or channel. Of course, this structure may not influence permeability or may affect it by providing parallel diffusional pathways or may be the sole diffusional pathway. Dispersed phases are embedded in continuous or shunt phases. They are discontinuous along the flux vector and do not provide an uninterrupted pathway through the membrane or through any of its subphases. If they are also discontinuous laterally, they are fillers that can be usually adopted to improve mechanical properties such as elasticity and resistance to tear. Netting is sometimes embedded in a membrane structure as a means of reinforcement. Since there can be phases within phases and phases, in turn, within these, it is necessary to designate whether a given identified phase is contributing to the coarsest structural breakdown (primary) or is a subphase of a primary or higher order phase. In this regards, each major phase identified must then be examined for the presence of secondary phases of each type and these, in turn, for tertiary phases, etc., until all distinct regions are accounted. Secondary phasic structure is common in real membranes. Recourse to characterization of tertiary and finer subclassification is generally unnecessary. Indeed, despite this complex frame, in the majority of the situations drug release field deals with polymeric membranes comprised of a continuous phase (usually a liquid phase) trapped in a swollen solid phase (polymeric network) [4]. This structure can be seen as a coherent system, having mechanical characteristics in between those of solids and liquids [5]. The presence of cross-links between polymeric chains hinders polymer dissolution in the liquid phase that can only swell the network. This structure is roughly similar to that of sponge filled by a liquid phase. Nevertheless, this is a particular sponge as, in the case of strong cross-links between polymeric chains (typically chemical covalent bonds), the network does not modify with time. When, on the contrary, weak cross-links prevail (typically physical interactions such as Coulombic, van der Waals, dipole-dipole, hydrophobic, and hydrogen bonding interactions), polymeric chains are not so rigidly connected to each other and the similarity with the sponge is no longer so pertinent. Indeed, while cross-link density (number of cross-links per unit volume) is constant with time (in static conditions), Brownian motion of chains and segment of chains makes the distribution of polymer-polymer junctions (cross-links) time dependent. As a consequence, while average dimensions of network meshes do not modify, each mesh can modify, thus resembling a statistical network. Obviously, this kind of network can easily undergo erosion due to polymer-polymer junction weakness. This physical frame is made more complex by the fact that the whole structure can be constituted by an ensemble of small matrix domains embedded in a continuum, usually represented by a polymer solution as it occurs for Carbopol [6,7]. Finally, the contemporary presence of two networks (interpenetrating structures), originated by two different polymers, can further complicate the scenario. Typically, these systems are produced by an initial swelling of a monomer, reacting to form a second intermeshing network structure [8,9]. Obviously, the choice of the polymer depends on the final administration route (examples include oral, ophthalmic, rectal, vaginal, and subcutaneous) and on different factors such as membrane swelling degree, biodiversity, biocompatibility, and interactions with drug, excipients, and mechanical properties.

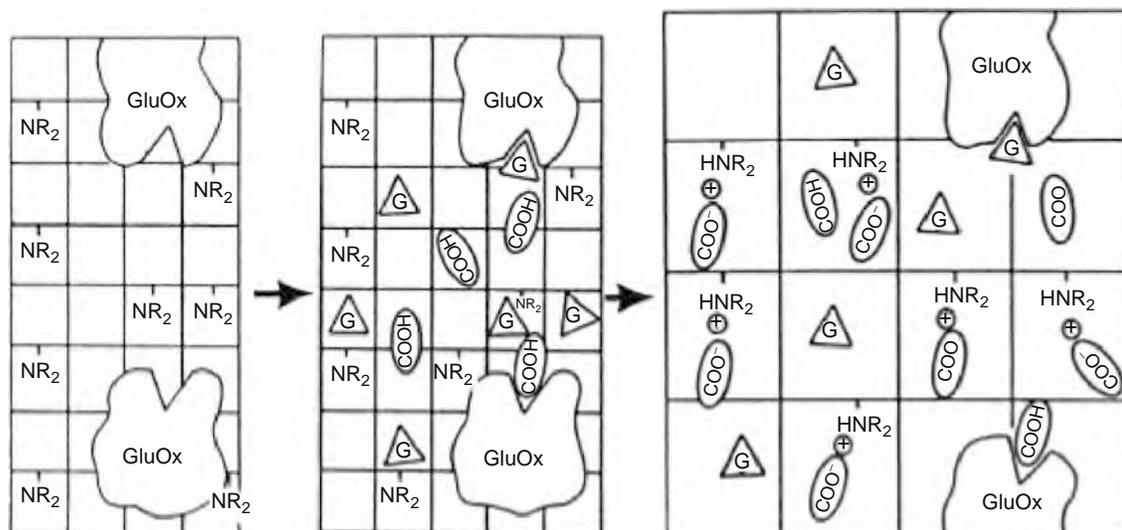

Despite the considerable wide application spectrum of membranes, typically, their use in the delivery field falls into drug release modulation based on a diffusive-controlled mechanism [10], isolation of particular structures from the external environment [11], making artificial implants biocompatible [12], allowing drug release (due to membrane dissolution) only when particular environmental conditions take place [13], and simulating the permeation properties of natural tissues [14-23]. At this purpose, it is interesting to consider some typical examples taken from the two most important delivery systems categories: externally regulated and self-regulated delivery systems [24]. For what concerns externally regulated systems, Miyazaki and coworkers [25] use ethylenevinyl alcohol membranes in reservoir-type drug delivery systems for the release of bovine insulin in the presence of ultrasounds. When diabetic rats receiving implants containing insulin are exposed to ultrasound ( $1 \text{ W/cm}^2$  for 30 min), a sharp drop in blood glucose levels is observed after the irradiation. This indicates a rapid rate of release of insulin in the implanted site. The authors attribute this behavior to temperature raising due to the radiating energy supplied. Okahata and coworkers [26,27], working on thermoresponsive delivery systems, use semipermeable nylon capsules prepared by interfacial polymerization (trimesoylchloride as a cross-linking agent) of ethylenediamine and terephthaloylchloride, or 1,10-decanedicarbonylchloride. NaCl-loaded capsules are transferred to dodecane solutions of dialkyl surfactant to introduce an amphiphilic bilayer on the capsule membrane. Remarkable permeability changes induced by

temperature changes are observed at the phase transition temperature, in contrast to the uncoated capsules. Bae and coworkers [28] working on insulin delivery report the use of thermosensitive hydrogel membranes constituted by poly(*N*-acryloylpyrrolidine) and its copolymers with styrene or 2-hydroxyethylmethacrylate cross-linked by ethyleneglycoldimethacrylate. The cross-linked poly(*N*-acryloylpyrrolidine) homopolymer shows thermosensitivity in water swelling, with weak mechanical strength, restricting its practical application to diffusion experiments. The incorporation of a hydrophobic monomer into the polymer improves the mechanical strength and lowers the overall swelling level as well as thermosensitivity. Accordingly, membrane composition and temperature represent two fundamental parameters for the achievement of the desired insulin delivery rate. In particular, insulin permeation through poly(hydroxyethyl methacrylate) increases with an increase in temperature. On the contrary, insulin permeation through poly(*N*-acryloylpyrrolidine) copolymers increases with a decrease in temperature.

Interestingly, membrane permeability can be modified by the action of an electric field. Indeed, electrophoretic migration of a charged macrosolute within a hydrated membrane depends on the effect of electrical forces acting on the solute and its counterions in the adjacent electrolyte solution [29]. It is well known that [30] four distinct electrochemical and electromechanical mechanisms concur in determining transport of proteins and neutral solutes across hydrogel membranes: (a) electrically and chemically induced swelling of a membrane to alter the effective pore size and permeability; (b) electrophoretic augmentation of solute flux within a membrane; (c) electroosmotic augmentation of solute flux within the membrane; and (d) electrostatic partitioning of charged solutes into charged membranes. In other words, the application of an electric field can result in control of solute flux by a combination of the electrophoretic and electroosmotic mechanisms. Pasechnik and coworkers [31] report an increase in the effective pore radius of ultrafiltration membranes due to electrodynamic effects. Burgmeyer and Murray [32] observe changes in the ionic permeability of polypyrrole redox membranes using a voltage-controlled electrochemical reaction. Eisenberg [33] can modify the restricted diffusion of sucrose through collagen membranes via electrodiffusion (this is due to effect of the electric field on concentration profiles within the membrane), obtaining flux changes up to 25%. Nussbaum [34] obtains reversible changes in the uniaxial swelling of poly(methyl methacrylate) (PMMA) membranes via electrodiffusion control of intramembrane ionic strength. Application of an electric field across a hydrated polyelectrolyte membrane, such as PMMA, yields to a net force on the space charge in the fluid phase, which contains an excess of counterions over coions. This force, transferred to the solvent, results in an electroosmotic fluid flow relative to the solid membrane. Grodzinsky [29] observes a volume flux of  $1.2 \times 10^{-6} \text{ m}^3/\text{s}$  at the direction of the current across a  $3.1 \text{ cm}^2$  PMMA membranes, fixing  $\text{pH} = 7$  and current density equal to  $320 \text{ A/cm}^2$ . As soon as the current is cutoff, the flow is stopped.

Mathiowitz [35–40] realizes reservoir-type delivery systems recurring to a photochemical control. Microcapsules, built up by interfacial polymerization of polyamide, also contain azobisisobutyronitrile, a substance that emanates nitrogen due to a photochemical action. Accordingly, after exposition to light, microcapsules' internal pressure increases (as a result of nitrogen release) until membrane rupture and consequent contents release.

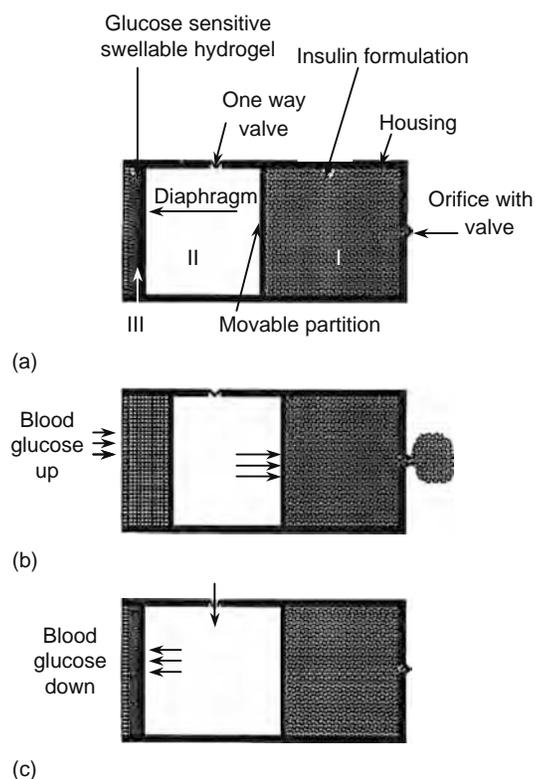

Self-regulated delivery systems [41] are closed loop-controlled devices in which the release is modulated by the system, in response to feedback information, excluding any external intervention. For example, it is possible to use pH as an environmental stimulus to deliver a drug in a desired gastrointestinal (GI) zone. Basically, the polymeric membrane ruling drug release rate from the delivery system can be poorly swollen and, thus, scarcely permeable with respect to drug, at a low pH (typical of stomach). On the contrary, if it shows a considerable swelling degree at higher pH, it allows drug release in the intestine where pH is considerable increased. A typical example of self-regulated delivery system using membranes concerns insulin delivery. Some authors suggest the immobilization of glucose oxidase in pH-responsive polymeric hydrogel membranes surrounding a saturated insulin solution (Figure 15.1). As soon as glucose penetrates into the membrane, glucose oxidase catalyses its conversion to gluconic acid. Consequently, pH lowering in the membrane microenvironment takes place. This pH decreases, determining membrane swelling, greatly improves permeability toward insulin that is copiously released. Horbett and coworkers [42], for example, use *N,N*-dimethylaminoethylmethacrylate (DMA), hydroxyethyl methacrylate (HEMA), and tetraethylene glycol dimethacrylate (TEGDMA). Membranes are prepared at  $-70^\circ\text{C}$  by radiation polymerization to preserve enzymatic activity. To get sufficient insulin permeability, HEMA-DMA polymerization is led in order to have a two-phase membrane: the continuous one is the polymer-rich phase, while the dispersed one contains solvent and unreacted monomers. When gelation occurs after the phase separation, the dispersed phase is fixed in the space to form of porous structure. Typically, pores diameter ranges between 1 and  $10 \mu\text{m}$  [43], and the addition of glucose provokes an insulin permeability increase equal to 2.4–5.5 times. Ishihara [44], following a similar approach, uses 2-hydroxyethylacrylate (HEA), *N,N*-dimethylaminoethylmethacrylate (DMA), and 4-trimethylsilylstyrene (TMS) by radical polymerization of the corresponding monomers in DMF. The mole fractions of HEA, DMA, and TMS in the copolymer are 0.6, 0.2, and 0.2, respectively. Membranes are prepared by solvent casting. Capsules containing insulin and glucose oxidase are prepared by an interfacial precipitation method using gelatin as an emulsion stabilizer. The average diameter of the polymer capsules obtained was 1.5 mm. Iwata and coworkers [45] pretreat porous poly(vinylidene fluoride) membranes (average pore size of  $0.22 \mu\text{m}$ ) by air plasma and subsequently acrylamide is graft polymerized on the treated surface. The polyacrylamide is then hydrolyzed to poly(acrylic acid). In the pH range of 5–7, grafted poly(acrylic acid) chains are solvated and dissolved, but cannot diffuse into the solution phase because of grafting to the porous membrane. Accordingly, membrane pores are effectively closed. In the pH range of 1–5, the chains

**FIGURE 15.1** Insulin release from glucose-sensitive membranes. (From Kost, J. and Langer, R., *Adv. Drug Deliv. Rev.*, 46, 125, 2001. With permission.)

collapse and the permeability increases. To achieve the sensitivity of the system toward glucose, glucose oxidase was immobilized onto a poly(2-hydroxyethyl methacrylate) gel.

Siegel and coworkers [46] approach insulin delivery by means of an implantable mechanochemical pump converting changes in blood glucose concentration into a mechanical force pumping insulin out of the device. Briefly, this device comprises three chambers (Figure 15.2): Chamber I contains an insulin solution, chamber II contains an aqueous fluid, while chamber III comprises a pH-sensitive polymer membrane that expands as glucose concentration increase. Chamber I is separated from the environment by a one-way valve opening when pressure in the pump exceeds that of the environment. Chamber II communicates with body fluids through a one-way valve opening when the pressure inside the pump

**FIGURE 15.2** Mechanochemical insulin pump. (From Kost, J. and Langer, R., *Adv. Drug Deliv. Rev.*, 46, 125, 2001. With permission.)

is less than that of the external medium. Hydrogel (Chamber III) is maintained in contact with the surrounding environment via a rigid membrane permeable only to small molecules and impermeable to large molecules, such as plasma proteins. Chambers II and III are separated by an elastomeric diaphragm, while chambers I and II are separated by a movable partition.

Of course, insulin release is not the unique target in the delivery field. Indeed, for example, Ishihara [47] matches the problem of urea release using a non-erodible membrane. The system is constituted by a pH-sensitive membrane (copolymerization of 4-carboxyacrylanilide and methacrylate) sandwiched among a membrane containing urease immobilized in free radically cross-linked *N,N*-methylenebisacrylamide. System permeability with respect to a model drug ((1,4-bis-(2-hydroxyethoxy)benzene) varies with urea concentration in the external environment.

Membrane-controlled devices, responsive to the concentration of external amines and amino acids, are prepared by polymerizing 2-hydroxy-dependent ethylmethacrylate and then reacting the polymer with 3,5-dinitrobenzoylchloride to attach 3,5-di-nitrobenzoate groups to the polymer [48]. Upon addition of amine substances to the external solution a charge-transfer complex forms, which increases the permeability of the membrane.

While the above-mentioned examples cannot be considered an exhaustive representation of all the possible uses of membranes in the delivery field, they serve to give an idea of how many and how variegated the applications can be. The aim of this chapter is to first describe the basic principles ruling mass transport through membranes. Then, in the light of the administration route (oral, transdermal, and implantable), some of the most important applications are presented and discussed. Finally, future applications of membranes in the delivery field are briefly treated.

## 15.2 MASS TRANSPORT

### 15.2.1 FACTORS AFFECTING DRUG PERMEATION

As most of the membranes used to modulate drug release kinetics are composed of polymers, this section focuses the attention on the typical mechanisms ruling mass transport through a polymeric network (whose structure has been previously described). At this purpose, it is necessary to first define the concept of membrane porosity as polymeric network can be classified as macroporous, microporous, and nonporous systems [49]. In the first two categories, drug diffusion occurs essentially through pores. For macroporous systems pores range between 0.1 and 1  $\mu\text{m}$ , which are much larger than diffusant molecules size. For microporous systems, pore size ranges between 0.005 and 0.02  $\mu\text{m}$ , which means, approximately, slightly larger than diffusant molecules size. Finally, nonporous systems have no pores and the molecules diffuse through network meshes. In this case, consequently, only the polymeric phase exists and no pore phase is present. While for macro- and microporous networks drug diffusion is mainly affected by pores topology; for nonporous structures, polymer swelling, polymer erosion, network topology, and drug/polymer interaction play the key role in determining drug diffusion. Indeed, it may happen that upon contact with the release environment, polymeric network undergoes a swelling process, particularly important in the case of a dry membrane. This implies molecular rearrangement of polymeric chains that tend to reach a new equilibrium condition as the old one was altered by the presence of the incoming external solvent [50]. The time required for this rearrangement depends on the relaxation time,  $t_r$ , of the given polymer/solvent system which, in turn, is a function of both solvent concentration and temperature. If  $t_r$  is much lower than the characteristic time of diffusion  $t_d$  of the solvent (defined as the ratio of the solvent diffusion coefficient at equilibrium and the square of a characteristic length), then solvent adsorption may be described by means of Fick's law with a concentration-dependent diffusion coefficient. On the contrary, if  $t_r$  is much greater than  $t_d$ , then a Fickian solvent adsorption with constant diffusivity takes place. Despite this complex phenomenology, however, in both cases the diffusion of drug molecules crossing the membrane may be described by Fick's law with a nonconstant diffusion coefficient (this is due to the variations of network meshes) and the macroscopic drug kinetics is defined Fickian. When  $t_r \approx t_d$ , solvent adsorption does not follow Fick's law of diffusion [51–53] and, consequently, also the diffusion of drug molecules crossing the membrane is not Fickian [54,55]. Accordingly, solvent absorption and drug permeation also depend on the polymer/solvent couple viscoelastic properties [56].

Polymer erosion can take place because of chemical and physical reasons. Under particular physiological conditions, the hydrolysis of eventually present water-labile bonds incorporated in the polymer can cause chain breaking. Moreover, erosion can also be due to enzyme attack and chemical reactions on particular polymeric chains sites [49]. On the contrary, in physically cross-linked matrices, erosion is due to chain disentanglement, induced by the matrix swelling fluid and the hydrodynamic conditions imposed in the release environment. Obviously, polymer characteristics play a very important role in erosion kinetics as extensively documented by the review of Miller-Chou and Koenig [57]. Erosion can be of two different types [49,58]: (a) surface or heterogeneous erosion and (b) bulk or homogeneous erosion. While in the first case only the outer parts of the matrix are affected by erosion, in the second case, the phenomenon also affects the polymeric bulk phase. Homogeneous erosion is usually due to a rapid swelling fluid uptake by the matrix system and consequent polymeric network degradation due to chemical reasons discussed above. On the contrary, surface erosion can be caused by both chemical (in this case the swelling fluid uptake is slower) and physical reasons, namely hydrodynamic conditions imposed in the release environment. On the basis of the relative chain cleavage and solvent diffusion rate, a system can be defined “surface eroding” or “bulk eroding.”

In particular, if solvent diffusion is much slower than polymer degradation, we are dealing with a surface eroding system. Surface erosion, also referred to as polymer dissolution in case of physically cross-linked matrices, can be further subdivided into two categories based on the amorphous and semicrystalline nature of the polymer. Indeed, while in the case of amorphous polymers only chain disentanglement is necessary for erosion, in the case of semicrystalline polymers, crystal unfolding precedes chain disentanglement, resulting in slower erosion kinetics [59].

Polymeric network topology heavily reflects on drug diffusion as it concurs in determining the drug diffusion coefficient as discussed later on. Additionally, polymeric network can also be responsible for a non-Fickian diffusion. Indeed, in presence of a very complex topology, deriving from a high internal disorder degree, the network can assume fractal characteristics [60]. If wide network meshes are defined as accessible sites for the diffusing drug and small network meshes (beside, obviously, polymeric chains) as forbidden sites, the entire network can be seen as a percolative network (fractal network), if forbidden sites approach a threshold value [61,62]. It is well known that diffusion on percolative (fractal) networks differs a lot from diffusion in non-fractal networks and release kinetics is different [60,63].

Although drug/polymer interactions can be expected to take place in several cases [64], particular importance is assumed by electrostatic interactions as reported by Singh and coworkers [65,66]. According to these authors, drug binding on polymeric chains follows a Langmuir isotherm mechanism characterized by an adsorption and desorption rates depending on drug free and bound concentration and on adsorption and desorption constants. Consequently, drug permeation through the membrane is the result of two phenomena, namely diffusion and adsorption–desorption.

### 15.2.2 CONTINUITY EQUATION

In the case of diffusion of a substance through a stationary solid or semisolid phase such as the polymeric network of a membrane, it is convenient to view the stationary phase as a fixed reference and to consider only the flux of mobile molecules, namely drug or external solvent. Assuming that the diffusion processes do not imply important variations of membrane density [50] and that no convective flux is present (this is the most common situation met in practice when dealing with membranes), mass conservation law reads [67]:

$$\frac{\partial C_i}{\partial t} = -\nabla \cdot F_i + R_i \quad (15.1)$$

where  $C_i$  and  $F_i$  are, respectively, the  $i$ th species concentration (mass/volume) and flux (mass/surface time),  $t$  is time,  $R_i$  is the  $i$ th component generation rate (mass/volume time), while the scalar product between the operator nabla  $\nabla$  and  $F_i$ , in a cartesian coordinate system, for the  $\nabla$  expression in other coordinate systems [see 67] reads

$$\nabla \cdot F_i = \left( \frac{\partial F_{xi}}{\partial X} + \frac{\partial F_{yi}}{\partial Y} + \frac{\partial F_{zi}}{\partial Z} \right) \quad (15.2)$$

where  $F_{xi}$ ,  $F_{yi}$ , and  $F_{zi}$ , respectively, are the  $x$ ,  $y$ , and  $z$  flux components relative to the  $i$ th species. Typically,  $F_i$  can be expressed according to Fick's law:

$$F_i = -D_i \nabla C_i \quad (15.3)$$

where  $D_i$  is the  $i$ th species diffusion coefficient. Accordingly, in a cartesian coordinate system,  $F_i$  components read

$$F_{xi} = -D_i \frac{\partial C_i}{\partial X}; \quad F_{yi} = -D_i \frac{\partial C_i}{\partial Y}; \quad F_{zi} = -D_i \frac{\partial C_i}{\partial Z} \quad (15.4)$$

As discussed in Section 15.3.1, it may happen that Equation 15.3 does not hold because of polymeric chains relaxation phenomena occurring during diffusion. In this case, indeed, the hypothesis of an instantaneous proportionality between  $F_i$  and  $\nabla C_i$  does not work and a time dependence has to be considered. Several approaches have been proposed to interpret this aspect. For instance, Joshi and Astarita assume a time-dependent composition at the polymer/penetrant interface [68]. In an interesting series of papers, Cohen first generalized Crank's idea [54] of a time-dependent diffusion coefficient [69], and then supposed that flux can be properly described by coupling the concentration and stress gradients, being the stress dependent on concentration and time via a Maxwell-like viscoelastic relationship [70]. Later on, Cohen and coworkers developed and improved the above-mentioned approach by modifying the stress dependence on time and concentration [71–73]. The existence of a stress-related convective contribution to flux is postulated by Frisch [74] and is also taken into consideration by other authors [75,76].

According to Adib and Neogi [77] and Camera-Roda and Sarti [78], the flux may depend on the history of the concentration gradient. The most general theory about diffusion in a viscoelastic polymer matrix was developed by Lustig [79], since he assumes that the flux depends on several driving forces such as temperature gradient, species' inertial and body forces, chemical potentials, and stress gradient. A good compromise between simplicity and theoretical correctness is given by the approach of Camera-Roda and Sarti [80]. Basically they assume that  $F_i$  may be expressed as the sum of two terms:  $F_{if}$ , characterized by a zero relaxation time and representing the Fickian contribution to the global flux, and  $F_{ir}$ , characterized by a nonzero relaxation time and representing the non-Fickian contribution to the global flux.

Accordingly,  $F_i$  can be expressed as

$$F_i = F_{ir} + F_{if}; \quad F_{if} = -D_{if} \nabla C_i; \quad F_{ir} = -D_{ir} \nabla C_i - \tau \frac{\partial F_{ir}}{\partial t} \quad (15.5)$$

where

$\tau$  is the relaxation time of the given polymer/diffusing molecule system

$D_{if}$  is the diffusion coefficient relative to the Fickian flux, while

$D_{ir}$  is the diffusion coefficient relative to the non-Fickian flux

In this approach, the time dependence is considered in the relaxation flux  $F_{ir}$ . Grassi and coworkers [50] improved the Camera-Roda and Sarti model assuming that  $F_{ir}$  is the sum of different contributes, each one characterized by its proper relaxation time. In this manner, the description of membrane viscoelastic properties is more adherent to reality.

While the time-dependent approach applies to describe possible membrane swelling (or deswelling) due to the presence of the external release environment fluid, it is not necessary in the case of drug permeation through a swollen membrane. The same is true when membrane swelling (or deswelling) is very fast or very slow in comparison to the duration of drug permeation through the membrane. A fast membrane swelling (or deswelling) will only reflect on a rapid drug diffusion coefficient variation.

### 15.2.3 DIFFUSION COEFFICIENT

Once an appropriate frame of reference is chosen, a two components (A, B) system may be described in terms of the mutual diffusion coefficient (diffusivity of A in B and vice versa). Unfortunately, however, unless A and B molecules are identical in mass and size, mobility of A molecules is different with respect to that of B molecules. Accordingly, the hydrostatic pressure generated by this fact will be compensated by a bulk flow (convective contribution to species transport) of A and B together, i.e., of the whole solution. Consequently, the mutual diffusion coefficient is the combined result of the bulk flow and the molecules random motion. For this reason, an intrinsic diffusion coefficient ( $D_A$  and  $D_B$ ), accounting only for molecules random motion has been defined. Finally, by using radioactively labeled molecules it is possible to observe the rate of diffusion of one component (let's say A) in a two component system, of uniform chemical composition, comprised of labeled and not labeled A molecules. In this manner, the self-diffusion coefficient ( $D_A^*$ ) can be defined [54]. Interestingly, it can be demonstrated that both  $D_A$  and  $D_A^*$  are concentration dependent. Indeed, the force  $f$  acting on A molecule at point X is [1]

$$f \propto -\nabla \mu_A \quad (15.6)$$

where  $\nabla \mu_A$  is the A chemical potential gradient. Accordingly, the total force  $f_T$  acting on all molecules is

$$f_T \propto -C_A \nabla \mu_A \quad (15.7)$$

where  $C_A$  is concentration. The assumption that the flux  $F_A$  is proportional to the total force yields to

$$F_A = -\frac{C_A}{\sigma_A \eta} \nabla \mu_A \quad (15.8)$$

where  $\sigma_A \eta$  is a resistance coefficient connected with diffusing molecules mobility [1,54]. Remembering the definition of chemical potential [81]:

$$d\mu_A = RT d(\ln(a_A)) \quad (15.9)$$

where

$a_A$  is the activity

$R$  is the universal gas constant

$T$  is temperature

it follows

$$F_A = -\frac{RT}{\sigma_A \eta} \frac{d(\ln(a_A))}{d(\ln(C_A))} \nabla C_A \quad (15.10)$$

Accordingly,  $D_A$  can be expressed by

$$D_A = \frac{RT}{\sigma_A \eta} \frac{d(\ln(a_A))}{d(\ln(C_A))} \quad (15.11)$$

Repeating the same treatment for  $D_A^*$  and remembering that in this case concentration and activity coincide due to obvious solution ideality, it follows that

$$D_A^* = \frac{RT}{\sigma_A \eta'} \quad (15.12)$$

assuming that  $\sigma_A \eta = \sigma_A \eta'$ , it descends that

$$D_A = D_A^* \frac{d(\ln(a_A))}{d(\ln(C_A))} \quad (15.13)$$

In conclusion, thus, the drug diffusion coefficient in a solvent is both concentration and temperature dependent. In the case of drug transport through swollen nonporous membranes, the physical frame is complicated by the presence of polymeric chains. Assuming that only drug molecules are moving due to a chemical potential gradient (in this sense, polymeric chains and the swelling agent molecules are retained immobile), the drug diffusion coefficient will be mainly affected by the presence of polymeric chains. Indeed, polymer chains have been proposed to retard solute movement by reducing the average free volume per molecule available to the solute, by increasing the hydrodynamic drag experienced by the solute, and by acting as physical obstructions thereby increasing the path length of the solute [82]. Basically, drug diffusion estimation can be performed recurring to the free volume theory, the hydrodynamic theory and to the obstruction theory [82]. Free volume theory [83] assumes that solute diffusion in a liquid is due to solute jumping into voids formed in the liquid space due to liquid molecules thermal motion. Solute diffusion is dependent on the jumping distance, the thermal velocity of the solute, and the probability that there is a hole free volume adjacent to the molecule. If, in addition, the presence of a polymeric network is considered, this theory yields, for example, to the model proposed by Peppas and Reinhart [84]:

$$\frac{D_g}{D_0} = k_1 \left( \frac{\overline{M}_c - \overline{M}_c^*}{M_n - \overline{M}_c^*} \right) \exp \left( -k_2 r_s^2 \left( \frac{\varphi}{1 - \varphi} \right) \right) \quad (15.14)$$

where

$D_g$  and  $D_0$  are, respectively, the solute diffusion coefficient in the polymeric network and in the swelling solvent

$k_1$  and  $k_2$  are the two constants

$\overline{M}_c$  is the number-average molecular weight between polymer cross-links

$M_n$  is the number-average molecular weight of the uncross-linked polymer

$\overline{M}_c^*$  is a critical molecular weight between cross-links

$\varphi$  is polymer volume fraction

$r_s$  is solute radius

Hydrodynamic theory [67], based on Stokes–Einstein equation, postulates that solute is represented by a very large sphere in comparison with the surrounding small liquid phase molecules. Solute mobility, and thus its diffusion coefficient, depends on the frictional drag exerted by liquid phase molecules. For heterogeneous gels (rigid polymeric chains), Cukier [85] suggests

$$\frac{D_g}{D_0} = \exp \left( - \left( \frac{3\pi L_c N_A}{M_f \ln(L_c/2r_f)} \right) r_s \varphi^{1/2} \right) \quad (15.15)$$

where

$L_c$  and  $M_f$ , are, respectively, the polymer chains length and molecular weight

$N_A$  is the Avogadro number

$r_f$  is the polymer fiber radius

For homogeneous gels (flexible polymeric chains), the same author proposes

$$\frac{D_g}{D_0} = \exp(-k_c r_s \varphi^{0.75}) \quad (15.16)$$

where  $k_c$  is a parameter depending on the polymer solvent system.

Models based on obstruction theory assume that the presence of impenetrable polymer chains causes an increase in the path length for diffusive transport. The polymer chains act as a sieve, allowing passage of a solute molecule only if it can pass between the polymer chains. Some authors [86], assuming solute molecule of the same size as polymer segments and assuming that solute transport occurs only within the free sites, suggest

$$\frac{D_g}{D_0} = \left( \frac{1 - \varphi}{1 + \varphi} \right)^2 \quad (15.17)$$

On the basis of more refined speculations, Ogston et al. [87] propose

$$\frac{D_g}{D_0} = \exp\left(-\frac{r_s + r_f}{r_f} \varphi^{1/2}\right) \quad (15.18)$$

According to Amsden [82], hydrodynamic approach should be used to deal with homogeneous hydrogels, while, for heterogeneous hydrogels, obstruction are more consistent with experimental data.

In the case of porous membranes, where solute diffusion takes place inside the liquid filling the pores, it is usual defining an effective diffusion coefficient  $D_e$ :

$$D_e = \frac{D_w \varepsilon}{\tau} \quad (15.19)$$

where

$\varepsilon$  is the matrix void fraction (porosity)

$\tau$  is tortuosity

$D_w$  is solute diffusion coefficient in the liquid filling the pores [88]

It is sometimes desirable [89] to incorporate into this expression a partition coefficient,  $K_p$ , for possible solute adsorption on pores walls and a restriction coefficient,  $K_r$ , accounting for hindered diffusion, and defined by

$$K_r = (1 - \lambda)^2 \quad \lambda = \frac{r_s}{r_p} \quad (15.20)$$

where  $r_p$  is the pore radius. Accordingly, Equation 15.19 becomes

$$D_e = D_w \frac{\varepsilon}{\tau} K_p K_r \quad (15.21)$$

#### 15.2.4 MODELING EXAMPLES: SWELLABLE AND NOT SWELLABLE MEMBRANES

Drug diffusion through a not swelling/deswelling/erodible (or through an already swollen) membrane can be described by means of Fick law. Indeed, assuming that drug concentration on one side of the membrane (donor environment) is always constant and equal to  $C_0$ , that drug concentration  $C_r$  on the other side (receiver environment) never sensibly detaches from zero (sink conditions), that drug diffusion takes place only in one dimension ( $X$ ), that membrane thickness is constant, that drug diffusion coefficient  $D_g$  inside the membrane is constant, and that no mass transport resistance exists at the membrane/donor and membrane/receiver interface (this means that, for example, we assume a negligible effect of the unavoidable presence of the stagnant layers sandwiching the membrane), Fick law solution yields (Equation 15.1):

$$C_r = \frac{C_0 K S}{V_r} \left( \frac{D_g}{h_m} t - \frac{h_m}{6} + \frac{2h_m}{\pi^2} \sum_{n=1}^{\infty} \frac{(-1)^n}{n^2} e^{-(n\pi/h_m)^2 D_g t} \right) \quad (15.22)$$

where

$t$  is time

$K$  is the partition coefficient

$S$  is the surface available for diffusion

$h_m$  is membrane thickness

$V_r$  is the receiver volume

For  $t$  approaching infinite, Equation 15.22 coincides with a straight line given by

$$C_r = \frac{C_0 SP}{V_r} (t - t_L); \quad P = \frac{KD}{h_m}; \quad t_L = \frac{h_m^2}{6D} \quad (15.23)$$

where

$P$  is the membrane permeability

$t_L$  is the lag time (intercept of Equation 15.23 on the  $t$  axis)

For thermoreversible gel membranes [90,91], the description of the swelling–shrinking phenomenon (induced by temperature changes) becomes paramount importance for what concerns a correct description of solute permeation. As mentioned in Section 15.3.2, a possible approach is that suggested by Camera-Roda and Sarti [80]. Accordingly, membrane swelling–shrinking can be described by Equation 15.5, provided that the following concentration dependence of  $D_f$ ,  $D_r$ , and  $\tau$  on solvent concentration  $C$  are considered

$$D_f = D_{in} \quad (15.24)$$

$$D_r(C) = D_{eq} \exp[g(C - C_{eq})] - D_{in} \quad (15.25)$$

$$\tau(C) = \tau_{eq} \exp[k(C_{eq} - C)] \quad (15.26)$$

where

$C_{eq}$  is solvent concentration in the swollen membrane ( $C = C_{eq}$ )

$D_{in}$  and  $D_{eq}$  are the diffusion coefficient of the solvent in the membrane at the beginning of the swelling phenomenon and at swelling equilibrium ( $C = C_{eq}$ ), respectively

$g$  and  $k$  are the two adjustable parameters

$\tau_{eq}$  is the membrane relaxation time when  $C = C_{eq}$

Equation 15.5 and Equations 15.24 through 15.26 have to be numerically solved [92] with the following:

Initial conditions

$$J = 0 \quad C = C_{eq}; \quad -L_{in}/2 \leq X \leq L_{in}/2 \quad (15.27)$$

Boundary conditions

$$C = C_{eq}; \quad X = \pm L_b/2 \quad (15.28)$$

where

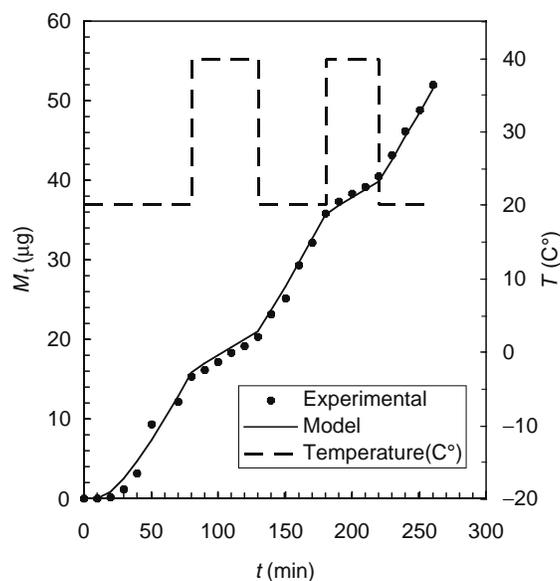

$L_{in}$  is the initial membrane thickness

$L_b$  is the position of the swelling membrane contours

Of course, membrane thickness can be calculated supposing that its volume is given by the arithmetic addition of solvent and polymer volume. Assuming that the most important effect of matrix swelling/shrinking is to modify the solute diffusion coefficient  $D_g$  (and the Peppas–Reinhart equation [Equation 15.14] can be considered to account for this), permeation can be described by the continuity equation (Equation 15.1) where the generative term  $R_i$  is set to zero and the following initial and boundary conditions hold:

Initial conditions

$$C_d = 0; \quad -L_{in}/2 < X < L_{in}/2 \quad (15.29)$$

**FIGURE 15.3** Model fitting of the hydrocortisone permeation through a swelling/deswelling copolymer (DMAEMA and AAm (molar ratio: 57% DMAEMA, 33% AAm)) gel undergoing step temperature variations. The permeated amount  $M_t$  is plotted as a function of time  $t$ . The dashed line indicates the temperature profile (From Grassi, M., Yuk, S.H., and Cho, S.H., *J. Membr. Sci.*, 152, 241, 1999. With permission.)

#### Boundary conditions

$$C_d = 0; \quad X = L_b/2 \quad (15.30)$$

$$C_d = C_s; \quad X = -L_b/2 \quad (15.31)$$

where  $C_d$  and  $C_s$  are, respectively, solute concentration and solubility, Equation 15.29 implies that the membrane is solute free at the beginning, Equation 15.30 accounts for sink conditions in the receiver and Equation 15.31 states that solute concentration in the donor is always constant and equal to solubility. Figure 15.3 shows the comparison between model best fitting (solid line) and experimental data relative to hydrocortisone permeation through a copolymer that comprises poly(*N,N*-dimethylaminoethyl methacrylate) (DMAEMA) and acrylamide (AAm) (molar ratio: 57% DMAEMA, 33% AAm). As this copolymer undergoes a sharp deswelling passing from 20°C to 40°C, hydrocortisone permeation is considerably decreased when temperature has risen to 40°C. Model best fitting reveals that hydrocortisone diffusion coefficient in the DMAEMA–AAm copolymer at 40°C is one tenth of that at 20°C.

### 15.2.5 OSMOTIC SYSTEMS

Osmosis is the natural movement of a solvent through a semipermeable membrane into a solution of higher solute concentration, leading to equal solute concentrations on both sides of the membrane [93]. A semipermeable membrane can be crossed by solvent molecules but solute (ionic or high molecular weight compounds) permeation is impeded. Solvent migration from one side of the membrane to the opposite one takes place to render equal solute and solvent chemical potentials across the membrane. Osmotic pressure  $\pi$  can be expressed by

$$\pi = \frac{(\mu_L - \mu_R)}{v} = -\frac{RT}{v} \ln(a) \quad (15.32)$$

where

$v$  is the solvent partial molar volume

$\mu$  is the solvent chemical potential on the left (initially solute-free environment) and on the right of the membrane

$a$  is the solvent activity on the membrane right side environment

When hydrostatic pressure in the right environment (initial solute richer environment) equals the osmotic pressure  $\pi$ , the net solvent flux ends. According to nonequilibrium thermodynamics, the rate of solvent transport  $dV/dt$  through the membrane is given by [94]:

$$\frac{dV}{dt} = \frac{A}{h} L_p (\sigma \Delta\pi - \Delta P) \quad (15.33)$$

where

$A$  is the cross-sectional area for transport

$h$  and  $L_p$  are the membrane thickness and hydraulic permeability, respectively

$\sigma$  is the reflection coefficient while  $\Delta\pi$  and  $\Delta P$  are the osmotic and hydrostatic pressure difference across the membrane

As, typically,  $\Delta P \ll \Delta\pi$ , Equation 15.33 simplifies into

$$\frac{dV}{dt} = \frac{A}{h} k \Delta\pi, \quad k = L_p \sigma \quad (15.34)$$

where  $k$  can be taken as the effective membrane permeability. Equation 15.34 is the basic equation for calculating the amount  $m$  of drug released from an osmotic pump. Indeed, since in an osmotic pump the volume of drug solution pumped out is equal to that ( $V$ ) of the external solvent entered in the pump through the semipermeable membrane, the rate of drug released will be

$$\frac{dm}{dt} = \frac{dV}{dt} c = \frac{A}{h} k \Delta\pi c \quad (15.35)$$

where  $c$  is the drug concentration of the solution contained in the osmotic pump housing.

### 15.2.6 ELECTROTRANSPORT

In order to improve drug permeation through skin, recourse to an electrical field can be made. On this idea, the electrically assisted delivery systems are based. Typically, electrotransport is due to iontophoresis, electroosmosis, and electroporation [95]. Iontophoresis consists in the use of an electric current to drive charged drug molecules into skin by placing them under an electrode of like charge. Accordingly, a positively charged drug should be placed under the anode or positive electrode and the resulting electric repulsion would provide the driving force for drug permeation through skin. Typically, a 0.5 mA/cm<sup>2</sup> current is used (this intensity being unable to cause skin damages) even if drug permeation can be modulated by acting on current intensity. Electroosmosis is the phenomenon according to which a bulk fluid flow rises when a charged porous membrane is subjected to a voltage differences. This fluid flow can be up to microliters per hour per square centimetres of hairless mouse skin [96]. Since skin is a perm-selective membrane with negative charge at physiological pH, the electroosmotic flow occurs from anode to cathode, increasing the flux of positively charged drugs. Unlike iontophoresis adopting a continuous low current, electroporation requires the use of high-voltage pulse for a very short duration to render the skin permeable. Probably, electroporation promotes the formation of new aqueous pathways (open for some microseconds and then closed for a time period ranging from milliseconds to hours) that allow the entry of drug molecules by diffusion and local electrophoresis or electroosmosis.

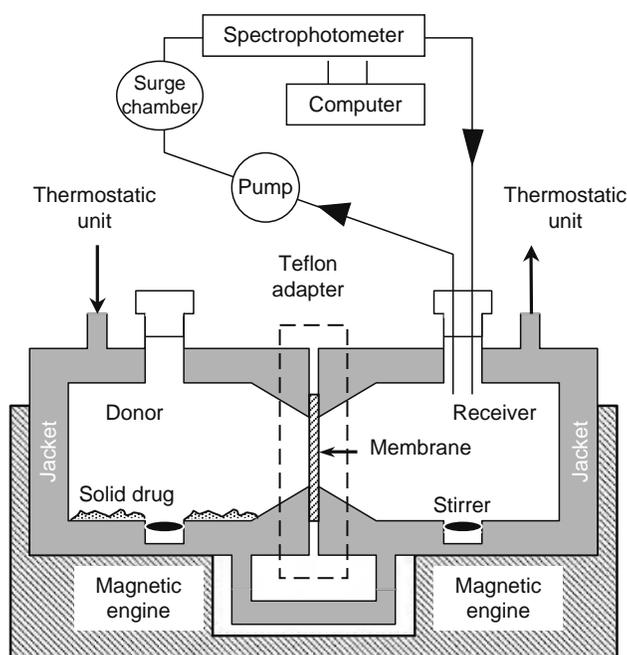

For iontophoresis, the flux  $F_i$  of an ionic species,  $i$ , is defined by the Nerst–Plank equation:

$$F_i = -D_i \nabla C_i - z_i m f C_i \nabla E \pm C_i V \quad (15.36)$$

where the first right-hand side term accounts for Fickian diffusion, while the second is relative to electrical field  $E$  effect and the third represents the electroosmotic flow. In particular,  $z_i$  is ionic species valence,  $m$  is mobility,  $f$  is Faraday constant, and  $V$  is the velocity of the convective electroosmotic flow. In order to get drug profile concentration, we have to solve the continuity equation (Equation 15.1), provided that Equation 15.36 is considered for the flux expression  $F_i$  and the generative term  $R_i$  is set equal to zero.

### 15.3 MEMBRANES: USEFUL DEVICE FOR DRUG DIFFUSION COEFFICIENT MEASUREMENT

In order to design a controlled release system based on membranes, it is of paramount importance to know the membrane drug diffusion coefficient,  $D$  [97]. Thus, the measure of  $D$  plays a very important role and the necessity of developing proper models able to interpret the experimental data arises. Several methods are available in literature for the experimental determination of  $D$  [98–100]. Among this plethora, I can mention the category of methods derived from nuclear magnetic resonance (NMR) and dynamic light scattering (DLS) experiments, those based on holographic relaxation spectroscopy, those founded on the determination of the drug concentration profile such as the sectioning and inverse sectioning method [101], and the methods based on drug concentration gradient under stationary and nonstationary gradient. This section, in particular, focuses on the  $D$  determination resorting to the analysis of drug permeation through a swollen membrane. At this purpose,

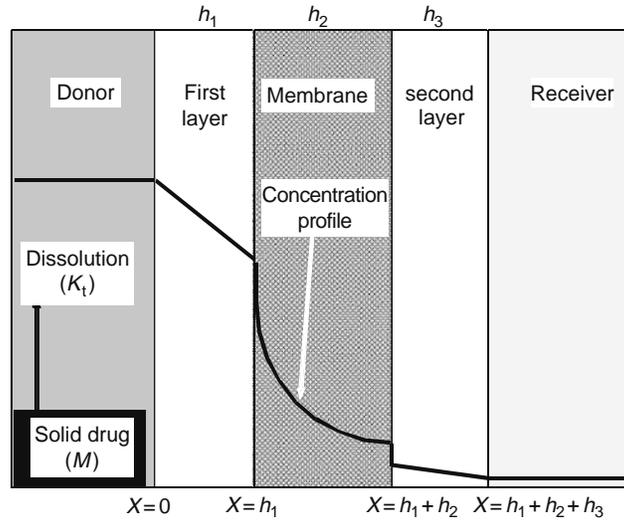

**FIGURE 15.4** Schematic representation of the side-by-side apparatus. The drug moves from the donor to the receiver compartment diffusing through the membrane and the receiver concentration increase is monitored and recorded by means of a personal computer managing an UV spectrophotometer. (From Grassi, M., Colombo, I., and Lapasin, R., *J. Control. Rel.*, 76, 93, 2001. With permission.)

the side-by-side apparatus is considered [102,103]. This device consists (see Figure 15.4) a donor compartment (volume  $V_d = 100 \text{ cm}^3$ ), containing the drug solution, and a receiver compartment (volume  $V_r = 100 \text{ cm}^3$ ) initially filled by pure solvent. Each compartment is equipped with a constant temperature jacket and a magnetic stirrer housed at the bottom of the cell. The membrane (diffusing area  $\approx 10 \text{ cm}^2$ ) is located in the teflon adapter connecting the receiver and the donor compartments. Drug concentration increase is measured and recorded by means of a personal computer managing a UV spectrophotometer connected to the receiver environment as indicated in Figure 15.4. In order to prevent bubble formation in the detecting system, a surge chamber is inserted between the spectrophotometer and the peristaltic pump, which provides for solution recirculation. A more sophisticated configuration permits the substitution of the recirculating system (peristaltic pump, surge chamber, etc.) with an optical fiber apparatus allowing a direct measurement of drug concentration in the receiver environment. The main advantages of this approach lie in the reduction of the receiver environment perturbation and the attainment of an optimal thermal control of the whole system.

### 15.3.1 NOT SWELLABLE MEMBRANES MODELING: EFFECT OF STAGNANT LAYERS AND DRUG DISSOLUTION

One of the most important errors affecting the determination of the drug diffusion coefficient resorting to permeation data through a swollen membrane may be due to the presence of two stagnant layers. Indeed, an insufficient stirring of both the donor and receiver environment gives origin to two stagnant layers sandwiching the membrane. Neglecting these two layers means to determine the value of the diffusion coefficient referred to the whole tri-laminate (comprised of the two stagnant layers and the membrane) instead of that referred to the single membrane. This implies an error depending on the sum of the thickness of the two stagnant layers. Sometimes this error may be not negligible, as the membrane thickness may be not small [104–106].

In order to make the present analysis as general as possible, it is assumed that the donor compartment contains an excess amount of undissolved drug. Indeed, this strategy is usually adopted in the attempt of achieving a constant drug concentration (in this case, drug solubility) in the receiver compartment. Accordingly, the drug dissolution process needs to be taken into account carefully. Nevertheless, it is assumed that Fick's law for diffusion holds inside the tri-laminate, which means that the effects of all possible chemical or electrical interactions between drug molecules and polymer chains or solvent molecules are accounted for by a drug partition coefficient (membrane/release environment medium) different from the value of one. Of course, a more detailed analysis should account for drug/polymer interaction by coupling, for instance, the diffusion with a drug adsorption–desorption phenomenon on polymer chains [107,108]. Anyway, the usual way to proceed [1,54,109,110] is to implicitly incorporate the polymer/drug interactions in the drug partition coefficient this being, in the majority of the situations, more than enough to correct model a permeation experiment. Furthermore, it is supposed that membrane is completely swollen, which means that the solvent concentration has reached its thermodynamic equilibrium value before starting the permeation

**FIGURE 15.5** Physical setup. A membrane is sandwiched among two layers arising in the donor and receiver compartments due to an insufficient stirring. In the donor volume, a dissolution process may take place. (From Grassi, M. and Colombo, I., *J. Control. Rel.*, 59, 343, 1999. With permission.)

experiments [111]. Indeed, membrane swelling may heavily influence the features of the drug permeation as previously discussed. Figure 15.5 schematically shows the physical setup with which all the following considerations will be referred to. Fick's second law for the first layer, the membrane and the second layer read, respectively:

$$\frac{\partial C_1}{\partial t} = \frac{\partial}{\partial X} \left( D_1 \frac{\partial C_1}{\partial X} \right) \quad (15.37)$$

$$\frac{\partial C_2}{\partial t} = \frac{\partial}{\partial X} \left( D_2 \frac{\partial C_2}{\partial X} \right) \quad (15.38)$$

$$\frac{\partial C_3}{\partial t} = \frac{\partial}{\partial X} \left( D_3 \frac{\partial C_3}{\partial X} \right) \quad (15.39)$$

where

$X$  is the abscissa

$t$  is the time

$C_1, C_2, C_3$  represent drug concentration in the first stagnant layer, in the membrane, and in the second stagnant layer, respectively

$D_1, D_2, D_3$  represent diffusion coefficient in the first stagnant layer, in the membrane, and in the second stagnant layer, respectively

Equations 15.37 through 15.39 must be solved with the following boundary conditions:

$$V_d \frac{dC_d}{dt} = -\frac{dM}{dt} + D_1 S \left. \frac{\partial C_1}{\partial X} \right|_{X=0} \quad (15.40)$$

$$\frac{dM}{dt} = -V_d K_i (C_s - C_d) \quad (15.41)$$

$$D_1 \left. \frac{\partial C_1}{\partial X} \right|_{X=h_1} = D_2 \left. \frac{\partial C_2}{\partial X} \right|_{X=h_1} \quad (15.42)$$

$$D_2 \left. \frac{\partial C_2}{\partial X} \right|_{X=h_1+h_2} = D_3 \left. \frac{\partial C_3}{\partial X} \right|_{X=h_1+h_2} \quad (15.43)$$

$$V_r \frac{dC_r}{dt} = -D_3 S \left. \frac{\partial C_3}{\partial X} \right|_{X=h_1+h_2+h_3} \quad (15.44)$$

$$C_1(X = 0) = K_{1d}C_d \quad (15.45)$$

$$C_2(X = h_1) = K_{21}C_1(X = h_1) \quad (15.46)$$

$$C_2(X = h_1 + h_2) = K_{23}C_3(X = h_1 + h_2) \quad (15.47)$$

$$C_3(X = h_1 + h_2 + h_3) = K_{3r}C_r \quad (15.48)$$

and the following initial conditions:

$$C_d = C_1 = C_{d0}; \quad C_r = C_2 = C_3 = 0; \quad M = M_0 \quad (15.49)$$

where

$C_d$  and  $V_d$  are, respectively, the drug concentration and volume of the donor compartment

$M$  is the time-dependent undissolved (solid) drug amount present in the donor compartment

$S$  is the area available for permeation

$K_t$  is the drug dissolution constant

$C_s$  is the drug solubility

$V_r$  is the receiver compartment volume

$h_1$ ,  $h_2$ , and  $h_3$  are, respectively, the thickness of the first stagnant layer, the membrane, and the second stagnant layer

$C_{d0}$  and  $M_0$  are, respectively, the initial drug concentration and undissolved drug amount in donor compartment, while  $K_{1d}$ ,  $K_{21}$ ,  $K_{23}$ , and  $K_{3r}$  are partition coefficients defined as follows:

$$K_{1d} = \frac{C_1(X = 0)}{C_d} = \frac{C_{1\infty}}{C_{d\infty}} \quad (15.50)$$

$$K_{21} = \frac{C_2(X = h_1)}{C_1(X = h_1)} = \frac{C_{21}}{C_1(X = h_1)} = \frac{C_{2\infty}}{C_{1\infty}} \quad (15.51)$$

$$K_{23} = \frac{C_2(X = h_1 + h_2)}{C_3(X = h_1 + h_2)} = \frac{C_{22}}{C_3(X = h_1 + h_2)} = \frac{C_{2\infty}}{C_{3\infty}} \quad (15.52)$$

$$K_{3r} = \frac{C_3(X = h_1 + h_2 + h_3)}{C_r} = \frac{C_{3\infty}}{C_{r\infty}} \quad (15.53)$$

where

$C_{d\infty}$  and  $C_{r\infty}$  are the drug concentration in the donor and receiver compartments

$C_{1\infty}$ ,  $C_{2\infty}$ , and  $C_{3\infty}$  are the drug concentration in the first layer, the membrane, and the second layer, respectively, after an infinite time

In this way, partition coefficients, defined by Equations 15.50 through 15.53, are thought concentration independent and, thus, time independent. Equation 15.40 represents the drug mass balance made up on the donor compartment: the first right-hand side term takes into account the dissolution, while the second represents the matter flux leaving the donor trough the first stagnant layer. Equation 15.41 takes into account the reduction of the solid drug  $M$  as the dissolution goes on. When  $M$  is zeroed, the first term of the right-hand side of Equation 15.40 vanishes. Equation 15.42 imposes that the matter flux leaving the first stagnant layer is equal to that entering the membrane ( $X = h_1$ ), while Equation 15.43 imposes the equality of the matter flux leaving the membrane and entering the second stagnant layer ( $X = h_2 + h_1$ ). Equation 15.44 represents the drug mass balance made up on the receiver compartment: the right-hand side term is the entering drug flux coming from the second layer. Equations 15.45 through 15.48 indicate the partitioning relation holding at the interface in  $X = 0$ ,  $h_1$ ,  $(h_1 + h_2)$ ,  $(h_1 + h_2 + h_3)$ . Equation 15.49 sets to zero the drug concentration in the membrane, the second layer, and the receiver while it sets to  $C_{d0}$  the drug concentration in the first stagnant layer and in the donor at the beginning of the permeation. An inspection of the above shown set of differential equations makes clear that the simpler situation represented by the absence of undissolved drug present in the donor compartment can be obtained by setting  $M_0 = 0$ .

If drug dissolution takes place from a thin tablet, it is reasonable to assume that  $K_t$  is time independent as dissolution surface is, practically, constant. On the contrary, if we are dealing with the dissolution of a powder, this is no longer true as particle radius and, thus, particle surface (this is the dissolving surface) reduce as dissolution proceeds. Indeed, the dissolution of a solid from a plane and uniform surface may be easily modeled by means of Equation 15.54 [112]:

$$V \frac{dC}{dt} = \frac{D_0 S_p}{h} (C_s - C) \quad (15.54)$$

where

$C$ ,  $C_s$ , and  $V$  are, respectively, the solute concentration, the solute solubility, and the volume of the dissolution medium

$S_p$  is the area of the solid/liquid interface

$D_0$  is the solute diffusion coefficient in the dissolution medium

$h$  is the thickness of the boundary layer arising between the solid surface and the dissolution medium

The thickness of the boundary layer,  $h$ , strongly depends on the stirring conditions of the dissolution medium [113,114]. Remembering that  $K_t$  is equal to

$$K_t = \frac{D_0 S_p}{hV}; \quad K_d = \frac{D_0}{h} \quad (15.55)$$

where  $K_d$  is the drug dissolution rate. Equation 15.54 may be recast in the following form:

$$V \frac{dC}{dt} = K_t (C_s - C)V \quad (15.56)$$

The right-hand side of Equation 15.56 coincides with the dissolution contribute employed in Equation 15.41. Since  $S_p$ , for a plane and uniform surface, does not change as dissolution develops, we may be sure that  $K_t$  is time independent. Unfortunately, this is not the case for a dissolving powder. Indeed, in such hypothesis, the dissolution surface decreases as the time goes on. The initial value of  $S_p$  and  $S_{p0}$  is equal to the powder surface area and, for a monodisperse powder made up of  $N_p$ , all equal, spherical particles, is given by

$$S_{p0} = N_p 4\pi R_0^2 \quad (15.57)$$

where  $R_0$  is the particle radius.

At time  $t$ , the particle radius will be decreased to  $R$  and, as a consequence,  $S_p$  will be equal to

$$S_p = N_p 4\pi R^2 \quad (15.58)$$

Then, the  $K_t$  time dependency will be given by

$$K_t = \frac{K_d}{V} 4\pi R^2 \quad (15.59)$$

Equation 15.59 holds the hypothesis that the whole powder surface is available for dissolution. This is reasonably accomplished when the dissolution medium is highly stirred so that the particles cannot adhere to the vessel walls or each other. Accordingly, the  $K_t$  time dependency, given by Equation 15.59, has to be inserted into Equation 15.40, getting

$$V_d \frac{\partial C_d}{\partial t} = 4\pi N_p R^2 K_d (C_s - C_d) + D_1 S \frac{\partial C_1}{\partial X} \Big|_{X=0} \quad (15.60)$$

Equation 15.60 has to be coupled with the  $R$  time dependency coming out from a mass balance made up on the tri-laminate, donor, and receiver compartments. This mass balance reads

$$M = M_0 + V_d(C_{d0} - C_d) - V_r C_r - \int_0^{h_1} C_1 S dX - \int_{h_1}^{h_1+h_2} C_2 S dX - \int_{h_1+h_2}^{h_1+h_2+h_3} C_3 S dX \quad (15.61)$$

Bearing in mind that

$$M = N_p M_p = N_p \frac{4}{3} \pi \rho R^3 \quad (15.62)$$

it follows

$$R = \sqrt[3]{\frac{3M}{N_p 4\pi\rho}} = R_0 \sqrt[3]{\frac{M}{M_0}} \quad (15.63)$$

where

$$M_0 = N_p \frac{4}{3} \pi R_0^3 \rho; \quad M_0 A = N_p 4\pi R_0^2 \quad (15.64)$$

where  $A$  is the powder surface per unit mass before dissolution. Equation 15.63 is the well-known Hixon–Crowell equation [115]. The effects of the  $K_t$  reduction are more evident when the dissolution phenomenon implies a considerable decreasing of the particle radius. Indeed, in this case, the dissolution surface will be strongly reduced and, as a consequence, the dissolving drug mass going into the donor compartment will be decreased. Obviously, the solution of the above set of equations (Equations 15.61 through 15.64) may be achieved only by means of a numerical method, for example, the control volume method [92] that is an implicit finite differences method suitable to solve such kind of problems.

Interestingly, if the drug concentration profile inside the two stagnant layers and the membrane has always a linear trend,  $K_t$  is time independent and the drug diffusion coefficient is concentration independent (these conditions are usually met for thin membranes and well stirred donor and receiver compartments), the proposed numerical model has the following analytical solution:

$$C_d(t) = A_1 + A_2 e^{(m_1 t)} + A_3 e^{(m_2 t)} \quad (15.65)$$

$$C_r(t) = B_1 + B_2 e^{(m_1 t)} + B_3 e^{(m_2 t)} \quad (15.66)$$

$$M(t) = M_0 + E_1 (e^{(m_1 t)} - 1) + E_2 (e^{(m_2 t)} - 1) \quad (15.67)$$

where  $A_1, A_2, A_3, m_1, m_2, B_1, B_2, B_3, E_1,$  and  $E_2$  are defined by the following equations:

$$m_1 = 0.5 \left( -(Tg - G + xb - Y) + \sqrt{(Tg - G + xb - Y)^2 - 4((xb - Y)(Tg - G) - Tzxa)} \right) \quad (15.68)$$

$$m_2 = 0.5 \left( -(Tg - G + xb - Y) - \sqrt{(Tg - G + xb - Y)^2 - 4((xb - Y)(Tg - G) - Tzxa)} \right) \quad (15.69)$$

$$A_1 = -\frac{(xb - Y)K_t C_s}{m_1 m_2} \quad (15.70)$$

$$A_2 = \frac{K_t C_s - \frac{(xb - Y)K_t C_s}{m_1} - (m_2 - (Tg - G))C_s}{m_1 - m_2} \quad (15.71)$$

$$A_3 = \frac{K_t C_s - \frac{(xb - Y)K_t C_s}{m_2} - (m_1 - (Tg - G))C_s}{m_2 - m_1} \quad (15.72)$$

$$B_1 = -\frac{K_t C_s + (Tg - G)A_2}{Tz} \quad (15.73)$$

$$B_2 = \frac{A_2}{Tz} (m_1 - (Tg - G)); \quad B_3 = \frac{A_3}{Tz} (m_1 - (Tg - G)) \quad (15.74)$$

$$E_1 = \frac{A_2}{m_1}; \quad E_2 = \frac{A_3}{m_2} \quad (15.75)$$

$$G = K_t C_s + \frac{D_1 S K_{1d}}{V_d h_1}; \quad T = \frac{D_1 S}{V_d h_1 K_{21}}; \quad x = \frac{D_3 S}{h_3 V_r K_{23}}; \quad Y = \frac{D_3 S K_{3r}}{h_3 V_r} \quad (15.76)$$

$$a = \frac{\gamma}{\alpha - \delta}; \quad b = \frac{\beta}{\alpha - \delta}; \quad g = \frac{\alpha\gamma}{\alpha - \delta}; \quad z = \frac{\delta\beta}{\alpha - \delta} \quad (15.77)$$

$$\alpha = 1 + \frac{D_3 h_2}{D_2 h_3 K_{23}}; \quad \beta = -\frac{D_3 h_2 K_{3r}}{D_2 h_3}; \quad \gamma = \frac{K_{1d}}{\frac{D_2 h_1}{D_1 h_2} + \frac{1}{K_{21}}}; \quad \delta = \frac{1}{\frac{D_1 h_2}{D_2 h_1 K_{21}} + 1} \quad (15.78)$$

To empirically adapt Equations 15.65 through 15.67 for the description of drug permeation through thick membranes, it is convenient to introduce a lag time  $t_l$  taking in account the time required to get a linear concentration profile in the two stagnant layers and in the membrane. Accordingly, it follows:

$$C_d(t) = A_1 + A_2 e^{(m_1(t-t_l))} + A_3 e^{(m_2(t-t_l))} \quad (15.79)$$

$$C_r(t) = B_1 + B_2 e^{(m_1(t-t_l))} + B_3 e^{(m_2(t-t_l))} \quad (15.80)$$

Equations 15.79 and 15.80 can describe the linear part of the permeation curve [116].

### 15.3.2 EXAMPLES: THEOPHYLLINE PERMEATION THROUGH CALCIUM ALGINATE MEMBRANES

For its large use in the pharmaceutical field, theophylline monohydrated ( $C_7H_8N_4O_2 \cdot H_2O$ ; Carlo Erba, Milano) can be used as model drug to measure the permeability of calcium alginate membranes having different thickness. Membranes are prepared by gradually adding the dry polymer powder (Protanal LF 20/60, Na salt of alginic acid; Protan Biopolymer, Drammen, Norway) into a highly stirred thermostatic (40°C) vessel containing demineralized water. In order to eliminate air bubbles produced by stirring, the solution undergoes a further mixing stage under vacuum for 5 min. The solution is put in a Petri disk, which in turn is immersed for 30 min in an aqueous solution containing 0.05 M  $CaCl_2$  and 0.4 M NaCl.  $CaCl_2$  represents the  $Ca^{++}$  source necessary for the gel formation (based on  $Ca^{++}$  mediated egg-box junctions [5,117]), while NaCl is added to guarantee a better gel homogeneity as suggested by Skiäk-Bræk et al. [117]. The gel membrane is washed for 2 min in demineralized water in order to remove salts from its surfaces and then its thickness is determined as the average of four measurements taken in different membrane points by means of an electronic calibre (Mitutojo, type IDC 112MCB, Japan).

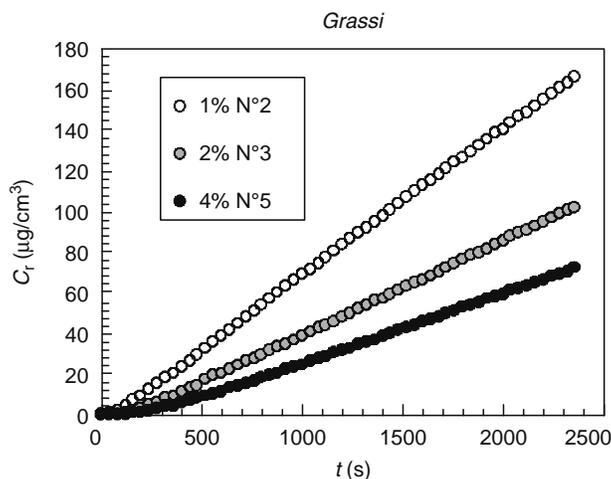

The side-by-side apparatus used (see Figure 15.4) is characterized by donor and receiver compartments having equal volumes ( $V_d = V_r = 100 \text{ cm}^3$ ) and a surface area  $S$  available for permeation of  $\sim 10 \text{ cm}^2$ . While, initially, the donor compartment contains a saturated theophylline solution in presence of not dissolved theophylline, the receiver compartment is initially filled by demineralized water. By means of the surrounding jacket, temperature is kept uniform and constant in the whole system while a magnetic stirrer (600 rpm) ensures good mixing in both the compartments. The drug concentration increase is measured and recorded by means of a personal computer managing an UV spectrophotometer (271 nm, UV (ultra violet)–VIS (visible) Spectrophotometer, Lambda 6, Perkin Elmer) connected to the receiver environment. Permeation experiments, led in duplicate, are performed at 25°C and 37°C, and for three different polymer concentrations (%P): 1, 2, and 4 w/w%. In order to get a reliable determination of the theophylline diffusion coefficient, all other model parameters have to be measured in advance [116]. In particular, theophylline water solubility  $C_s$  ( $6681 \pm 42 \text{ } \mu\text{g}/\text{cm}^3$  at 25°C;  $12495 \pm 104 \text{ } \mu\text{g}/\text{cm}^3$  at 37°C), its water diffusion coefficient  $D_w$  ( $6.1 \pm 0.4 \times 10^{-6} \text{ cm}^2/\text{s}$ , 25°C;  $8.2 \pm 0.6 \times 10^{-6} \text{ cm}^2/\text{s}$ , 37°C), the powder dissolution constant  $K_d$  ( $= 1.57 \times 10^{-3} \text{ cm}/\text{s}$ , 25°C;  $1.52 \times 10^{-3} \text{ cm}/\text{s}$ ,  $T = 37^\circ\text{C}$ ), the partition coefficient  $K_m$  between the membrane (calcium alginate gel) and the donor–receiver fluid (water) and, finally, the thickness  $h_1$  and  $h_3$  of the two stagnant layers (see Table 15.1)

are determined. Figure 15.6 shows the trend of the receiver drug concentration  $C_r$  vs. time  $t$ , for the test performed at  $25^\circ\text{C}$  at three different %P (test N° 2, 3, 5). The difference between the curves obtained from tests 2 and 3 is mainly due to different values of  $D_2$ , since membrane thickness is comparable (see Tables 15.1 and 15.2), while in the case of test 5 membrane thickness is the key parameter governing the difference. Moreover, the nonlinear trend in the beginning part of the curves, regardless the %P value, indicates that the membranes under consideration cannot be defined as thin. Depending on the %P considered, after a sufficiently long time, the permeation curves assume an almost linear trend indicating that, correspondingly, a linear drug concentration profile is attained inside the tri-laminate (two stagnant layers and membrane). Similar considerations can be done for Figure 15.6 where the  $C_r - t$  trend refers to  $T = 37^\circ\text{C}$ . Alginate does not give origin to thermosensitive hydrogels and, hence, an increase in temperature does not lead to appreciable changes in the membrane structure, whereas, the theophylline diffusion coefficient increases with temperature. Accordingly, the permeation kinetics is improved at  $37^\circ\text{C}$  and  $C_r$  increases more rapidly than at  $25^\circ\text{C}$ . An inspection of Table 15.2 reveals that the theophylline diffusion coefficient ( $D_2$ ) does not sensibly vary with %P, regardless temperature. This can be explained with the fact that the %P increase, in the 1%–4% range, does not substantially reflect in an increase of the polymeric network cross-link density, responsible for a reduction of the

 $T$  is the temperature and %P is the polymer percentage in the membrane.

**FIGURE 15.7** Best fitting of the numerical (thick solid line) and linear (thin solid line) models on the experimental data (open circles) referring to test No. 5 (membrane polymer concentrations [w/w %]  $\%P = 4\%$ ,  $T = 25^\circ\text{C}$ ). The two models best fitting practically coincide in the linear part of the curve. (From Grassi, M., Colombo, I., and Lapasin, R., *J. Control. Rel.*, 76, 93, 2001. With permission.)

network mesh size, but it reflects in a higher membrane thickness. Nevertheless, it cannot be also excluded that, due to reduced theophylline dimension ( $\approx 3.8 \text{ \AA}$  [116,118]), polymeric network meshes are always very large even in the case  $\%P = 4$ . Obviously, this result cannot exclude that for higher polymer concentration, typical of some polymeric pharmaceutical membranes,  $\%P$  increase does not reflect in a, reasonable, cross-link density increase.

Finally, it is interesting to note that the results obtained by fitting Equations 15.79 and 15.80 (being  $t_r$  and  $D_2$  the only fitting parameters) on experimental data are, practically, equal to those deducible by fitting the numerical model to the same data (see Table 15.2). Figure 15.7 shows the good agreement between experimental data (open circles) and model best fitting (thick solid line, numerical model; thin solid line Equations 15.79 and 15.80).

## 15.4 ORAL DELIVERY SYSTEMS

Oral administration is the most popular route due to ease of ingestion, pain avoidance, versatility, (to accommodate various types of drug candidates), and, most importantly, patient compliance [119]. In addition, solid oral delivery systems do not require sterile conditions and are, therefore, less expensive to manufacture. Orally delivered pharmacologically active compounds must have favorable absorption and clearance properties, and satisfactory metabolic stability to provide adequate systemic exposure to elicit a pharmacodynamic response. If the compounds possess reasonable physicochemical properties have low to intermediate clearance and reasonable absorption, adequate oral bioavailability may be achieved [120]. Indeed, oral bioavailability, defined as the rate and extent to which the active drug is absorbed from a pharmaceutical form and becomes available at the site of drug action [121], is influenced by several factors including solubility, permeability, intestinal and liver metabolism, rapid biliary and other efflux pump-mediated excretion, and conditions in the gastrointestinal milieu [122,123]. Thus, both absorption and elimination processes determine the oral bioavailability  $F$  of a given drug. Accordingly,  $F$  can be estimated as

$$F = F_a F_g F_h F_l \quad (15.81)$$

where

$F_a$  is the fraction absorbed across the intestinal wall

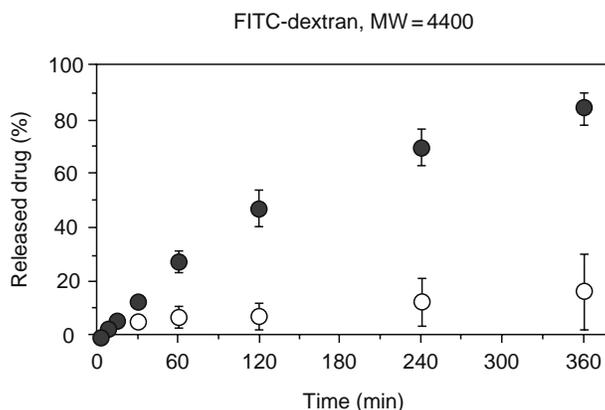

$F_g$ ,  $F_h$ , and  $F_l$ , are, respectively, the fractions escaping clearance by the gastrointestinal tract, liver, and lung

The product of fraction available after gut and liver extraction ( $F_g F_h$ ) following oral administration primarily determines the oral clearance of the drug, although the contribution of lung clearance should also be considered [124]. It is therefore clear that, due to the complexity of drug absorption, the designing of drug release kinetics is of paramount importance and membranes can play an important role in oral delivery systems that are diffusion and dissolution controlled, as well as in ion exchange resins and osmotic systems. Indeed, apart from the simple taste masking aim (but this aspect becomes very important when dealing, for example, with delivery systems devoted to pediatric applications), typically, membranes are used in oral delivery systems to modulate release kinetics by controlling drug diffusion in the release environment or by controlling external solvent penetration

in the delivery system. Additionally, membrane can be designed to dissolve in particular physiological conditions to ensure drug release in the stomach rather in the intestine or vice versa depending on the drug absorption window. For example, Verapamil (calcium channel blocker, indicated for the hypertension treatment), a water-soluble compound that does not show bioavailability problems, can be administered by means of both reservoir systems (Verelan capsules, Elan Corporation, Gainesville, Georgia) and osmotic pumps (Searle's Covera-HS tablets, Alza Corporation, Palo Alto, California). Verelan contains a mixture of rapid and slow release beads [125] coated by a polymeric film consisting an hydroxypropylmethylcellulose/ethylcellulose blend that is applied in standard coating pan by spraying the coating suspension onto the core beads. The final commercial capsules, containing 20% uncoated beads and 80% coated beads, show a totally pH-independent release kinetics [126]. Covera-HS is designed to be administered at bedtime while active drug release takes place 4–5 h from ingestion as, in general, high blood pressure for many patients with myocardial infarction occurs early in the morning. This device comprises two chambers: the active drug core and the osmotic push compartment. Delayed release is achieved by the presence of an interposed membrane (enteric coating material) between the drug active core and the semipermeable membrane (cellulose acetate, hydroxypropylcellulose, polyethylene glycol). Indeed, the osmotic mechanism does not start until the GI tract water has completely dissolved the enteric coating material.

Nifedipine, another antihypertension drug belonging to the calcium channel blockers, is poorly soluble in water. Accordingly, an effective administration of this drug must be based on erosion or osmotic pressure mechanism. While the osmotic pump (Procardia XL tablets) device adopts the same membranes seen in the Verapamil release (Covera-HS), the erosion driven delivery consists in a compress-coated system. The inner portion (core) contains micronized nifedipine plus various excipients (among which lactose, corn starch, microcrystalline cellulose), while the external membrane is comprised of hydroxypropylcellulose, lactose, and nifedipine. As soon as this delivery system is put in contact with the release environment, the hydroxypropylcellulose hydrates and the soluble lactose erodes allowing nifedipine release at a constant rate. After, approximately 8 h, the external membrane is completely dissolved and the immediate dissolution of the inner core takes place, yielding a very fast release of the remaining nifedipine dose.

Another interesting application of membranes is shown in the work of Järvinen and coworkers [13] who study drug release from pH and ionic strength responsive poly(acrylic acid) (PAA) grafted poly(vinylidene fluoride) (PVDF) membrane bags in vitro. Square-shaped bags ( $2 \times 2$  cm) are formed by placing two PVDF membranes (Millipore; pore size  $0.22 \mu\text{m}$ ) on top of each other and hot-sealing three sides to get a membrane bag. The open side serves to insert model drug inside the bag after grafting. Bags are irradiated with 25 kGy under nitrogen atmosphere and the unsealed side is protected with a copper plate to avoid hot-sealing after grafting. Immediately after irradiation, bags are immersed at room temperature in a graft solution containing AA that is continuously purged with nitrogen to remove oxygen. Then, bags are Soxhlet extracted with water to remove any remaining monomer and dried overnight. Finally, bags are filled manually with model drug (FITC-dextran) and the open side is hot-sealed. The United States Pharmacopeia (USP) 23 rotating basket method (100 rpm,  $37^\circ\text{C}$ ,  $900 \text{ cm}^3$  of dissolution medium: 6 mM phosphate buffer at pH 2.0 or 7.0. The ionic strength is adjusted to 0.15 with NaCl) is used to study release kinetics from bags. Figure 15.8 shows that FITC-dextran release is considerably higher at pH 2.0 than at pH 7.0. Indeed, this is due to changes in the conformation of the grafted PAA chains as a function of pH. As PAA pKa is about 4 [127], at pH 2.0, polymer chains are undissociated resulting in a compact conformation. Accordingly, the pores of the PVDF-PAA membrane are open and the drug can pass through. On the contrary, at pH 7.0, PAA molecules are dissociated and swollen so that pores are partially blocked and drug passage is hindered. On the same principle it is based on the application of Li and

**FIGURE 15.8** Release of FITC-dextran from membrane bags prepared from 50 wt% PAA grafted PVDF membranes into dissolution medium at pH 2.0 (filled circles) and pH 7.0 (open circles). (From Järvinen, K., Åkerman, S., Svarfvar, B., Tarvainen, T., Viinikka, P., and Paronen, P., *Pharm. Res.*, 15, 802, 1998. With permission.)

D'Emanuele [128] who synthesizes cross-linked poly(NIPAAm) hydrogel (thermoresponsive polymer) within the pores of sintered glass filter discs using an in situ free radical polymerization method. At 40°C, poly(NIPAAm) is in the shrunken state so that pores are open and model drug (salicylic acid) permeation is high. On the contrary, at 20°C, poly(NIPAAm) is in the swollen state and pores are filled by the gel that hinders model drug (salicylic acid) permeation. In this manner, the authors can control drug release kinetics acting on temperature.

The aim of this section is to illustrate some coating techniques based on physical and physicochemical principles. In addition, for their potentiality, the attention will be then focussed on asymmetric membranes and on membranes devoted to colon-specific delivery systems.

#### 15.4.1 MEMBRANES FOR PHYSICALLY COATED SYSTEMS

Typically, aqueous and organic techniques can be used to coat solid dosage forms. In general, the choice of aqueous polymer dispersions implies various advantages, such as reduced toxicity and lower processing times, with respect to organic polymer solutions. In addition, aqueous approach, despite much higher polymer concentration, yields to coating formulation characterized by relatively low viscosities compared to those of the respective organic coating solutions. However, aqueous approach suffers for sensitivity to several factors—such as temperature, pH, addition of electrolytes, and other polymers—which, potentially, can lead to dispersion destabilization and coagulation. Obviously, coating properties coming from aqueous or organic techniques are neatly different and this, in turn, is the result of different film formation mechanisms. In the organic solution, macromolecules, highly mobile and interpenetrated (spaghetti like configuration), undergo solgel transition upon solvent evaporation to get film formation. Accordingly, homogeneous and compact films are realized. On the contrary, in the aqueous strategy, polymer particles are dispersed in the liquid and, upon water evaporation, they get well organized on the dosage form solid surface to form close-packed arrays. Capillary forces then drive the particles to coalesce together. Usually, the addition of a plasticizer is required to minimize film formation temperature, making particles softer and facilitating their coalescence. Consequently, film microstructure differs from that of organic-based film and crack formation is, generally, more probable [129].

In both the organic and aqueous approaches, release kinetics from coated systems is not an easy process as many variables, such as water diffusion, polymer swelling and dissolution, drug dissolution, diffusion, and cracks formation through the coating can play a key role [130]. In addition, the use of polymer blends in coating formation, although allowing a broad variety of drug release patterns, makes the release kinetics scenario much more complicated. Indeed, nowadays limited knowledge is yet available on the importance of the coating technique strategy (aqueous or organic) in the case of polymeric blends. Nevertheless, it seems clear that, in blend coatings, the effect of film formation mechanism on film structure and, thus on release kinetics, is more important than in the case of one polymer coating [131].

For example, Lecomte and coworkers [129] study the characteristics of propranolol hydrochloride (Abbot, Ludwigshafen, Germany) loaded pellets (10% w/w loading) coated by a blend of water-insoluble (ethyl cellulose (EC); Ethocel Standard 10 Premium, Dow Chemical Company, Midland, Michigan) and enteric polymers (methacrylic acid–ethyl acrylate copolymer 1:1, Eudragit L100-55, Röhm, Darmstadt, Germany). Triethyl citrate (TEC, Morflex, Greensboro, North Carolina) is used as plasticizer. Drug-loaded pellets are coated with EC and Eudragit L100-55 ethanolic solutions and blends thereof or with the respective aqueous polymer dispersions. EC:Eudragit L blend ratios investigated are 0:100, 25:75, 50:50, and 100:0 w/w, while 0.1 M HCl and phosphate buffer pH 7.4 are the release environments considered in the USP XXV paddle apparatus (37°C). Spraying technique is used to coat the loaded pellets. In virtue of the higher degrees of entanglements, dry films coming from organic solutions show better mechanical properties (energy at break and elongation) for all the blend ratios considered. In addition, dry film mechanical properties do not sensibly depend on plasticizer content. For what concerns release properties, the authors find that release kinetics strongly depends on the coating technique considered (organic or aqueous) and a great variety of release patterns can be obtained by varying blend ratios. In particular, for organic coating, release kinetics increases with Eudragit L content and it is improved by higher pH values. Conversely, in the case of aqueous coating, if pH increase still reflects in improved release kinetics, the effect of Eudragit L content on release kinetics is no longer (increasing) monotone. Finally, wherever low-pH release kinetics from aqueous coating is higher than the organic coating, these differences practically vanishes at high pH where the most important aspect is enteric polymer dissolution.

On the other hand, Siepmann and coworkers [130] focus attention on release kinetics from aqueous coating technique. In particular, theophylline pellets ( $\approx 800 \mu\text{m}$  diameter; Boehringer Ingelheim, Ingelheim, Germany) coated by two different kinds of water-insoluble and enteric polymers: (a) EC (Aquacoat ECD, FMC c/o Interorgana, Köln, Germany) and hydroxypropyl methylcellulose acetate succinate HPMCAS (ShinEtsu c/o Syntapharm, Mühlheim and er Ruhr, Germany); and (b) EC and Eudragit L30D-55 (Röhm, Darmstadt, Germany) are considered. Triethyl citrate (TEC, Morflex, Greensboro, North Carolina) is used as plasticizer. Blend ratios and release apparatus are the same used by Lecomte [129] and Siepmann and coworkers. At low pH, the authors find that release kinetics from EC:Eudragit L and EC:HPMCAS coated pellets is similar and it increases with HPMCAS or Eudragit L content, respectively. At high pH, regardless of the coating type, release kinetics is improved due to the partial dissolution of the enteric polymer. Nevertheless, this is more evident in the EC:Eudragit L coating irrespective of

blend ratio. The authors demonstrate that this is due to the high presence of water-filled cracks in the EC:Eudragit L coating. This affirmation is also supported by mechanical tests on films exposed to high pH release environment (higher energy is required to break EC:HPMCAS films).

It is now interesting to focus the attention on the different techniques used in the coating process. Typically, it involves deposition of uniform polymeric membrane onto the surface of the substrate such as tablets, pellets, or drug particles. Film coating, layering coating, and compressed coating represent the most used techniques [126]. Film coating process is performed in a coating pan, a fluidized bed, or a rotary granulator. Ethylcellulose, methacrylic ester copolymers, methacryl ester copolymers, cellulose acetate, and enteric polymers are widely used either alone or in combination with water-soluble polymers for the preparation of controlled release films. Since the integrity of the film and the absence of flaws or cracks are important factors in controlling the drug release kinetics from such preparation, it is very important that film formulation is optimized. In the light of this, plasticizers are often added to increase flexibility and to reduce the incidence of flaws. Obviously, coating properties also strongly depend on the presence of pigment and solvent, and on process variable such as temperature, spray rate, and so on. Layering coating is often performed in a fluidized bed in a noncontinuous manner. In coating beads, for instance, the seeds may first be coated with one layer of active drug and then with one polymeric layer followed by another active drug layer to get a wafer structure. In some cases, the active drug may be dissolved or dispersed with the coating materials. Compression coating process is performed using a tablet press to make a compress coat surrounding a tablet core (tablet-in-tablet). The compress coat can act as a barrier to drug release or as a part of formulation to provide biphasic release. Initially the process needs to compress the core formulation to get a relatively soft tablet that is then transferred in a larger die for final compression of the compress coat layer. This process can be used to develop a controlled release system with unique release profiles or to formulate two incompatible drugs by incorporating one in the core and the other in the compress coat layer.

Among the novel technologies, electrostatic coating merits to be considered [119]. The interesting advantage of this dry coating process consists in the elimination of blending powders, granulation, drying, lubrication and compression. In addition, it is less operator-dependent, it is continuous and is considerably fast. The principle of electrostatic deposition is based on the fact that opposite charges attract. Material deposition occurs when a pattern of charges is established on the substrate where the deposition is desired, and a supply of material to be deposited is delivered in the form of small, charged particles. The pattern of charges on the substrate will establish an electrical field,  $E$ , that interacts with charges on the material to be deposited according to Coulomb's Law:

$$F = qE \quad (15.82)$$

where

$F$  is the force

$q$  is the charge

The charged particles will be moved by this force, transported to the substrate, and deposited in a pattern determined by the charge on the surface. The key components in the technology may be summarized as four main areas, namely, active pharmaceutical ingredients, substrate, electrostatic chuck, and the controlled field deposition process. For what concerns active ingredients, the technology allows the production of material with controlled size, morphology, uniform flow, and charging properties. Intrinsic surface properties of active ingredients can be modified to enhance charging and handling. The substrate, an insulating film, is defined as the base upon which the drug is deposited. The substrate mechanical properties, such as thickness, modulus, and strength, and the electrical property of bulk resistivity are critical [132]. A chuck is a clamp or a device that holds an object. The role of an electrostatic chuck is to hold the substrate and provide the charged pattern onto the substrate in this technology. The electrostatic chuck can be equipped with an electrode for sensing the number of particles attracted to the chuck, thereby ensuring an accurate amount of particles [133]. Finally, the charging is achieved by using a three layer structure that has a conducting back-plane electrode, an insulating layer, and a patterned conducting top electrode. This controlled field deposition process enables the material to be directly deposited onto a single layer substrate [134]. The electrostatic powder coating process implies electro-charged powder adhesion on a rotating charged cylinder. Then, the powder is put into close proximity to the tablets (to be coated) that are vacuum-held in depressions around another cylinder. An opposite charge is given to the powder by means of a high-tension electrode to transfer it on the exposed tablet surface. Powder fusion to form a film is achieved by brief exposure to a source of long-wave infrared radiation.

#### 15.4.2 MEMBRANES FOR PHYSICOCHEMICALLY COATED SYSTEMS

In contrast to previous paragraph, in this case, coating process can also involve a chemical reaction and this approach can be generally named as microencapsulation. Microencapsulated solid preparations are widely used in pharmaceutical, chemical, and other industries to protect various substances from environmental impact, as well as for extending their action [135]. In the

pharmaceutical field, in particular, these preparations are mainly used to get controlled release drug kinetics, to minimize side effects, to reduce gastric irritations, and to mask the unpleasant taste of the contained drug [135–140]. Indeed, many different active components are microencapsulated: analgesics, antibiotics, antihistamine, cardiovascular agents, iron salts, antipsychotics [141], vitamins, peptides [142], proteins [143], anti-asthma [138,144], broncodilators, diuretics, anticancerogens, tranquilizers, and antihypertensives [135].

Basically, microencapsulation can be performed according to the interfacial polymerization technique and the coacervation/phase separation methods [135,145]. The first approach consists polymerization of a monomer at the interface between two immiscible phases yielding to the formation of a solid film surrounding the dispersed phase (termed microcapsule core or simply core). This technique applies in the case of water-immiscible liquid core, water-miscible liquid core, and solid core. For instance, in the case of a water-miscible liquid core, a hydrophilic polymer aqueous solution is dispersed in an organic phase with the aid of an emulsifier to get a water-in-oil emulsion. The addition of a water-insoluble reactant in the organic phase promotes the polymerization and thus the formation of a solid film around the aqueous dispersed phase. As the penetration of reactants in the polymerization zone is easier in a liquid environment than in a solid one, interfacial polymerization is more suitable for liquid encapsulation. Typically, polyamides, polyesters, and polyurethanes films are realized by using various combinations of water- and oil-soluble monomers and solvents [145]. Microcapsules morphology is characterized by a continuous and smooth external film, while an inner irregular surface is generally encountered. Microcapsules of 20–30  $\mu\text{m}$  diameter (even if smaller 3–6  $\mu\text{m}$  diameter capsules can be produced) characterized by a 20 nm film thickness can be obtained.

The coacervation/phase separation methods can be divided into aqueous and organic groups. In turn, aqueous group can be divided into complex and simple [135]. Simple coacervation, applying only for the microencapsulation of solid and liquid hydrophobic materials, implies the dissolution of a hydrophilic polymer in water where, subsequently, the hydrophobic core is dispersed. Encapsulation occurs due to the deposition of the coacervate (polymeric colloidal phase) on the hydrophobic core following a variation in temperature/pH or the addition of a precipitating agent. While complex coacervation differs from simple coacervation for the presence of more than one colloid, organic coacervation is the inverse of the aqueous one. Indeed, in this case, the core is constituted by a water-soluble material, while the film is an hydrophobic material. Among the many polymers that are used in the coacervation technique, agar, albumin, alginates, chitosan, collagen, pectin, and starch can be remembered for what concerns natural polymers, while acrylic acid, cellulose derivatives, polyurethanes, polyamides, and polyvinylpyrrolidone represent the synthetic part. Typically, microcapsules ranging from 5 up to 5000  $\mu\text{m}$  can be produced while elastic or rigid and fragile or tough films can be obtained.

To achieve maximum efficiency from using microencapsulated particles, it is necessary to know the time needed to extract the solid phase out of the polymeric capsule. The extraction rate of active components through a polymeric coating depends on many factors such as the nature of the polymeric film binder, the conditions under which the coating was applied, its structure, thickness, and porosity [146]. As a consequence, to properly design these particular delivery systems, a deep knowledge of the release mechanism and of the drug–film physical properties is required [147,148]. Indeed, drug release occurs from an ensemble of poly-dispersed spherical particles constituted by an external polymeric film that can undergo both erosion and swelling upon contact with the release environment. In addition, drug dissolution in the inner core (in the case of solid core) and drug diffusion in the film concur to determine the release kinetics. Indeed, as soon as microparticles are put in contact with the release environment, the external fluid crosses the polymeric coating, progressively dissolves the drug core, and fills the inner void space generated by core dissolution. Consequently, the drug present in the inner solution moves through the polymeric film determining the increase of its concentration in the release environment. Thus, drug is distributed among outer solution (release environment), polymeric coating, inner solution, and solid core. Despite the industrial relevance of microencapsulated delivery systems, no many authors matched the mathematical modeling of these systems, probably due its complexity. Nevertheless, some interesting examples can be found in literature [139,146,149,150].

### 15.4.3 ASYMMETRIC MEMBRANES

Asymmetric membranes are composed of a thin, dense skin layer supported by a thicker, porous substructure layer (Figure 15.9). Accordingly, they combine the high selectivity of dense membranes with the good permeability of porous membranes and thin dense membranes [151]. The technique used to produce these particular membranes implies the dissolution of the desired polymer in a solvent mixture composed by at least two solvents. One will be a good solvent for the polymer (more volatile solvent), while the other (less volatile solvent) will be a poor solvent (or non-solvent) for the polymer. Upon evaporation, due to different solvents boiling point, the solution enriches in the less volatile solvent (poor solvent) causing an abrupt precipitation of the polymer [152]. This technique (phase inversion) implies the transformation from a solvent continuous phase to a polymer continuous phase. Indeed, as soon as the drying process develops from the original solvent phase, two inter-dispersed liquid phases grow up. Then, further drying leads to a primary and secondary gel. The initial solvent solution contains also a third solvent (pore former) that has a non-solvent character for the polymer and that is neatly less volatile than the other two solvents. An alternative process implies polymer dissolution in a solvent system, film casting, and subsequently immersion into a quench bath of non-solvent for polymer. The solvent of the first step is extracted from the cast

**FIGURE 15.9** Scanning electron micrograph showing the cross-section of the asymmetric membrane wall. (From Thombre, A.G., Cardinal, J.R., DeNoto, A.R., and Gibbes, D.C., *J. Control. Rel.*, 57, 65, 1999. With permission.)

polymer solution into the quench bath, which leads to the precipitation of the polymer in structured form. In order to infer the desired elasticity and to reduce brittleness to asymmetric membrane, hydrophobic/hydrophilic plasticizers (glycerol, diethyl phthalate) may be added to the coating formulation.

In the delivery field, asymmetric membranes are typically employed as semipermeable membranes in osmotic-controlled delivery systems. Even if the drug release mechanism is mainly governed by the difference in osmotic pressure between the environmental fluid and drug-containing core of the delivery system, the diffusion contribute through the membrane cannot, in principle, be neglected. As soon as the delivery system is put in contact with the external delivery environment, water penetrates the asymmetric membrane, dissolves the inner core-soluble compounds (among which the drug and the osmotic agent), and pumps out drug solution through membranes pores due to increased internal pressure. As asymmetric membrane is not perfectly semipermeable, part of the drug can be delivered also by diffusion. Accordingly, the drug release rate ( $dM/dt$ ) is given by

$$\frac{dM}{dt} = \frac{dM_o}{dt} + \frac{dM_d}{dt} \quad (15.83)$$

where

$t$  is time

$M$  is the total drug amount released until  $t$ ,  $M_o$  and  $M_d$  are the  $M$  contribute due to osmotic pressure difference and diffusion, respectively

According to Equations 15.35 and 15.3, Equation 15.83 becomes:

$$\frac{dM}{dt} = \frac{A}{h} k \Delta \pi c + AD \frac{c}{h} \quad (15.84)$$

where

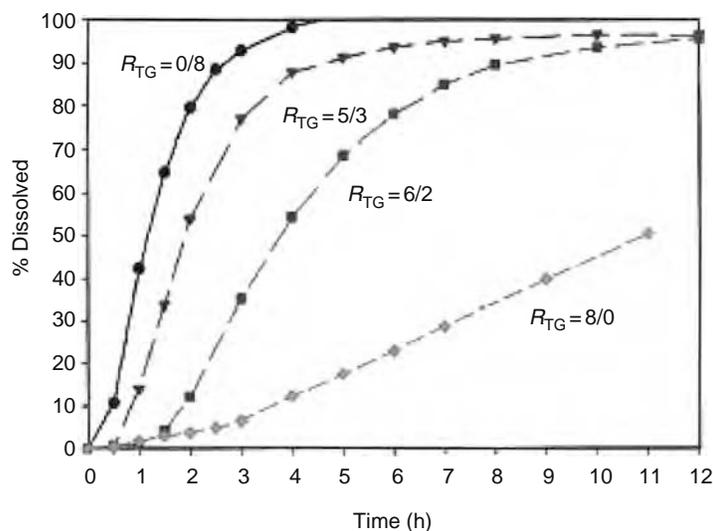

$A$  and  $h$  are device surface area and membrane thickness, respectively

$k$  is the membrane permeability (with respect to water)

$\Delta \pi$  is the osmotic pressure difference

$c$  is the dissolved drug concentration in the core fluid, while  $D$  is drug diffusion coefficient inside the asymmetric membrane

With respect to other osmotic technologies, asymmetric membranes ensure higher water permeability reflecting in the possibility of greater designing flexibility. Indeed, fast release rate can be achieved and lower solubility drugs can be

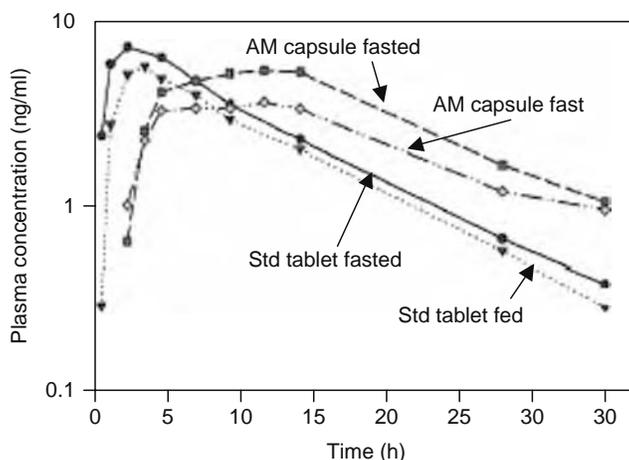

**FIGURE 15.10** Dissolution of glipizide from asymmetric membrane capsules as a function of the wall membrane permeability depending on triethylcitrate (TEC)/glycerol ratio  $R_{TG}$ . (From Thombre, A.G., Cardinal, J.R., DeNoto, A.R., and Gibbes, D.C., *J. Control. Rel.*, 57, 65, 1999. With permission.)

considered. Then, not only membranes porosity can be controlled by choosing the proper pore former, but also asymmetric membranes can be produced by means of conventional pharmaceutical equipment [151]. Typically, polymers such as cellulose derivatives, polysulfones, polyamides, polyurethanes, polypropylene, poly(vinyl chloride), polyvinyl alcohol, poly(vinylidene fluoride), ethylenevinyl acetate, ethylenevinyl alcohol, and PMMA are used to fabricate asymmetric membranes [153]. On the technological side, it has to be remembered that asymmetric membranes can be used to produce capsule shells and tablets by dip-coating process followed by immersion into a quench bath or air drying process [153]. In addition, they can be used to coat beads ( $\approx 1$  mm diameter) by means of the spray-drying and conventional spray-coating technique.

An interesting study about in vitro and in vivo performances of asymmetric membranes is given by Thombre and coworkers [154]. These authors, starting from a standard coating solution (cellulose acetate 15%, acetone 49%, ethyl alcohol 28%, and glycerin 8% [plasticizer, variable: 0%–8%], triethylcitrate [TEC] [variable: 0%–8%]), manufacture capsules, filled by drug, based on a dip-coating process [155]. The in vitro dissolutions are performed using standard USP dissolution methodology (Apparatus 2, rotating paddles, 50 rpm, 37°C, and 900 or 1000 mL of medium). The pharmacokinetic studies are performed in four fasted and fed laboratory beagle dogs using an immediate release tablet as the control. In vitro results clearly evidence how the more soluble the drug the higher the release rate. In addition, the authors observe that membrane permeability decreases with increasing TEC concentration. Indeed, higher amount of TEC reflects in a thicker dense membrane layer. This aspect is well documented by Figure 15.10 showing the percentage of glipizide released from capsules characterized by an increasing TEC concentration. For the in vivo performance of asymmetric membranes (same composition of in vitro test apart from the percentage of glycerin 3% and triethylcitrate 5%) doxazosin (1.5 mg dose) is used as a model drug. Figure 15.11 shows the comparison between mean plasma concentration due to standard immediate release tablets used as the control (Std tablet) and asymmetric membrane capsules (AM Capsules). Four laboratory beagle dogs in fed and fasted conditions are considered. It is clear that AM capsules alter doxazosin pharmacokinetics by reducing the concentration peak and prolonging absorption ( $T_{max} = 59.0$  h fasted and 7.0 h fed).

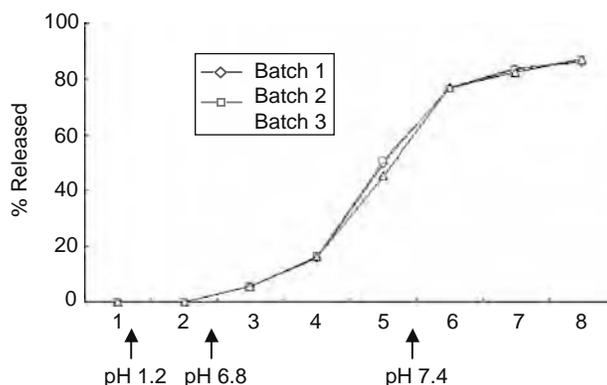

#### 15.4.4 MEMBRANES FOR COLON DELIVERY

Membranes play a fundamental role also in the colon-specific drug delivery systems. This administration route, whose advantages have been well recognized and documented [156], provides more effective therapy of colon-related diseases such as irritable bowel syndrome, inflammatory bowel disease (IBD) including Crohn's disease and ulcerative colitis. Colon-specific delivery has the potential to address important unmet therapeutic needs including oral delivery of macromolecular drugs. The colon is also viewed as the preferred absorption site for oral administration of protein and peptide drugs, because of the relatively low proteolytic enzyme activities in the colon. For example, insulin, calcitonin and vasopressin can be absorbed in that region [157]. Because of the distal location of colon in the GI tract, a colon-specific drug delivery system should prevent drug release in the stomach and small intestine, and effect an abrupt onset of drug release upon entry into the colon. This necessitates a triggering element in the system that can respond to physiological changes in the colon. Basically, the traditional

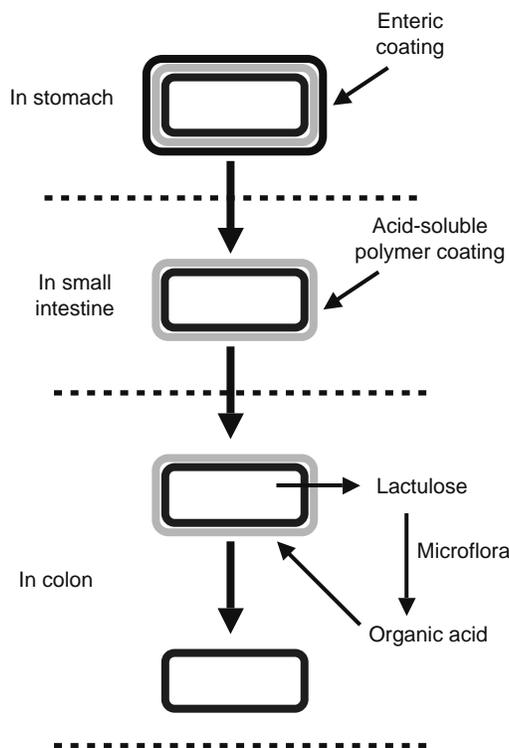

**FIGURE 15.11** Comparison between mean plasma doxazosin concentrations relative to –1 mg standard tablet (Std tablet) and 2 mg asymmetric membrane capsules (AM Capsules). Four laboratory beagle dogs in fed and fasted conditions are considered. (From Thombre, A.G., Cardinal, J.R., DeNoto, A.R., and Gibbes, D.C., *J. Control. Rel.*, 57, 65, 1999. With permission.)

four approaches to colon delivery are pro-drugs, pH-dependent systems, time-dependent systems, and microflora-activated systems [156]. Membranes, typically, are involved in the last three situations. For example, LiuXing [158] studies the delivery of bee venom peptide loaded on liposomes contained in an Eudragit S100 coated calcium alginate beads. Drug release studies are carried out using a USP Dissolution Rate Test Apparatus (Apparatus 1, 100 rpm, 37°C). The coated calcium alginate gel beads are tested for drug release for 2 h in 0.1 M HCl (250 mL), as the average gastric emptying time is about 2 h. Then, the dissolution medium is replaced with pH 6.8 phosphate buffer (250 mL) and tested for drug release for 3 h, as the average small intestinal transit time is about 3 h. Next, pH 7.4 phosphate buffer (250 mL) is used to test drug release for 3 h. As Eudragit S100 dissolves at  $\text{pH} \geq 6.8$ , it is expected that peptide release takes place only after 2 h. Indeed, after coating dissolution, gel beads are exposed to the aqueous environment that promotes polymer matrix swelling and erosion, leading to the liposome-loaded peptide release. Figure 15.12 shows that while the initial release of bee venom from the coated gel beads is very low, it considerably increases later on. Bee venom release in the first 2 h is negligible ( $\text{pH} 1.2$ ), while the fractional drug amount released rises to 5.5% after 3 h and 16% after 4 h. After 8 h, about 90% is released. Siew and coworkers [159] study 5-aminosalicylic acid release from amylose–ethylcellulose coated pellets in batch culture fermentation systems containing amylase enzymes or fecal bacteria. The pellets (100 g batch size) are coated in a fluidized bed coater (GPCG-1 Uni Glatt, Glatt GmbH, Binzen, Germany) using an amylose–ethylcellulose mixture containing 50% amylose to a total weight gain of 15%. The mixture is sprayed at a rate of 0.3 g/min through a 1.1 mm nozzle under a pressure of 2 bars. The bed temperature is maintained at 40°C. These authors find that the rate of release of 5-aminosalicylic acid is slightly faster in the fecal fermentation system than in the enzyme system, although release in both systems is substantially faster than in the control. This proves that the amylose coating can be destroyed by the presence of proper enzymes that can be produced by fecal bacteria. These findings are substantially confirmed both in vitro and in vivo (four healthy volunteers) also by Macleod and coworkers [160] who work

on pectin-chitosan-hydroxypropyl methylcellulose (3:1:1) film coated radiolabelled ( $^{99m}\text{Tc}$ ) tablets. For both in vitro and in vivo tests, tablets are provided by an outer enteric coating (hydroxypropyl methylcellulose phthalate). The gastrointestinal transit of the tablets is assessed by gamma scintigraphy while a Caleva dissolution apparatus is used for in vitro release (pectinolytic enzyme is added to Sorensen's phosphate buffer to mimic colon environment). The experimental results show that tablet breakup starts once tablets are in the colon, due to degradation of the coat by colonic bacteria. Basically, this example falls in the so-called CODES approach [156] that couples the action of outer pH-sensitive coatings and an inner bacteria degradable coating as illustrated in Figure 15.13. Three polymeric layers surround the tablet core. The first coating (next to the core tablet) is an acid-soluble polymer (for example, Eudragit E) and outer coating is enteric with a HPMC barrier layer in between to prevent any possible interactions between the oppositely charged polymers. The core tablet is comprised of the active, one or more polysaccharides and other desirable excipients. The polysaccharides, degradable by enterobacteria to generate organic acid, include mannitol, maltose, stachyose, lactulose, fructooligosaccharides, etc. During its transit through the GI tract, CODES remains intact in the stomach due to the enteric protection, but the enteric and barrier coating will dissolve in the small intestine, where the pH is above 6. Because Eudragit E starts to dissolve at  $\text{pH} \leq 5$ , the inner Eudragit E coating is only slightly permeable and swellable in small intestine. Upon entry into the colon, the polysaccharide inside the core tablet will dissolve and diffuse through the coating. The bacteria will enzymatically degrade the polysaccharide into organic acid. The consequent pH lowering is sufficient to affect the dissolution of the acid-soluble coating and the following drug release.

Among newly developed colon-specific drug delivery systems, pressure-controlled delivery capsules (PCDCs) [161] can be mentioned. Their mechanism of action is based on the relatively strong peristaltic waves taking place in the colon and leading to an increased luminal pressure. They consist of a capsular-shaped suppositories coated with a water-insoluble polymer (ethyl cellulose). Once taken orally, PCDCs behave like an ethyl cellulose balloon, because the suppository base liquefies at body temperature. In the upper GI tract, PCDCs are not directly subjected to the luminal pressures since sufficient fluid is present in the stomach and small intestine. The reabsorption of water in the colon provokes an increase of the luminal content viscosity. As a result, increased intestinal pressures directly affect the system via colonic peristalsis. Consequently, PCDCs rupture and drug release in the colon take place.

## 15.5 TRANSDERMAL DELIVERY SYSTEMS

As skin is one of the most readily accessible organs of the body, topical application of drugs for treatment of skin diseases or pathology has been studied for a long time [162]. Indeed, skin separates the vital organs from the outside environment and

**TABLE 15.3**  
**Characteristics of Transdermal Patches**

Drug	Product Name	Dose and Patch Size	Dose Delivered	Clinical Indication
Clonidine	Catapres-TTS	2.5–7.5 mg in 3.5–10.5 cm <sup>2</sup>	0.7–2.1 mg in 7 days	Hypertension
Ethinylloestradiol(EO) norelgestromin (N)	Ortho-Evra	0.75 mg EO and 6 mg N in 20 cm <sup>2</sup>	0.14 mg EO and 1.05 mg N in 7 days	Birth control
Fentanyl	Duragesic	2.5–10 mg	1.8–7.2 mg in 3 days	Analgesia
Lidocaine	Lidodem	700 mg in 140 cm <sup>2</sup>	10–32 mg in 12 h	Post-herpetic neuralgia
Lidocaine (L) epinephrine (E)	Iontocaine	20–50 mg/L and 10–25 µg E in 5.7–11.1 cm <sup>2</sup>	40 mAmin iontophoresis	Dermal anesthesia
Nicotine	Habitrol Nicoderm-CQ Nicotrol Prostep	8.3–114 mg in 3.5–30 cm <sup>2</sup>	5–22 mg in 16–24 h	Smoking cessation
Nitroglycerin	Nitro-Dur Transderm- Nitro	12.5–160 mg in 5–40 cm <sup>2</sup>	1.2–11.2 mg in 12–14 h	Angina

serves as a protective barrier against physical, chemical, and microbial attacks. Though these good protective properties, often topical applications represent a successful drug delivery strategy. Indeed, for many drugs, the transdermal route has the potential to be an extremely efficient delivery site [163]. Topical application avoids the effects of both gastric degradation and hepatic first-pass metabolism, and it presents a large surface area for absorption (~2 m<sup>2</sup>) and has relatively low proteolytic activity [163]. Accordingly, today there exist a number of patches for drugs such as clonidine, fentanyl, lidocaine, nicotine, nitroglycerin, oestradiol, oxybutynin, scopolamine, and testosterone [164,165]. There are also combination patches for contraception, as well as hormone replacement (see Table 15.3). In addition, transdermal administration can represent an opportunity to avoid side effects as it happens in the case of oestradiol patches (used by more than a million patients annually) that, in contrast to oral formulations, do not cause liver damage [166]. Similarly, transdermal clonidine, nitroglycerin, and fentanyl patches exhibit few adverse effects than conventional oral dosage forms. Despite this encouraging frame, however, some problems connected with the transdermal route still remain. Indeed, only low molecular weight (MW < 500), high lipophilicity (oil soluble), and small required dose (up to milligrams) drugs can be successfully administered. The smallest drug presently formulated in a patch is nicotine (MW = 162) and the largest is oxybutynin (MW = 359). Opening the transdermal route to large hydrophilic drugs is one of the major challenges in the field of transdermal drug delivery. Indeed, the possibility of releasing drugs such as proteins and peptides would lead to considerable advantages in terms, for example, of patient's health and compliance. In the light of this, the most clinically significant protein is, of course, insulin. Due to the chronic nature and multiple daily-dosing requirement of its administration schedule and the population of diabetics in the world, providing a noninvasive delivery mechanism for this compound would represent a considerable improvement from both the patient and the manufacturer viewpoint. However, other macromolecules such as cyclosporin, luteinizing hormone-releasing hormone (gonadotrophin-releasing hormone), and thyrotropin-releasing hormone could take advantage of a transdermal administration. Finally, also vaccines could be administered by means of the transdermal route and this assumes a very important aspect if we remember that the World Health Organisation currently recommends that children be immunized with approximately 12–13 different vaccines before 1 year of age which, in addition to the discomfort associated with needle injections, also raises issues about the potential risk of transfer of blood-borne pathogens [163]. Accordingly, the possibility of delivering such large molecules through the skin in a painless way, and yet still achieve sufficient cellular response to elicit immune protection, would be very important. Fortunately, large molecule release through skin may now be possible with some of the physical enhancement technologies. Consequently, the target of this section is to illustrate some examples of transdermal drug delivery focussing on passive diffusion-regulated delivery systems and systems aided by physical enhancing methods.

### 15.5.1 MEMBRANES FOR PASSIVE DELIVERY SYSTEMS

As skin has evolved to impede the flux of toxins into the body and minimize water loss, it shows very low permeability to the penetration of foreign molecules [167]. A unique hierarchical structure of lipid-rich matrix with embedded corneocyte in the upper strata (15  $\mu\text{m}$ ) of skin—the stratum corneum—is essentially responsible for this barrier. The corneocytes, comprising cross-linked keratin fibers, are  $\sim 0.2\text{--}0.4$   $\mu\text{m}$  thick and  $\sim 40$   $\mu\text{m}$  wide [168]. They are held together by corneodesmosomes, which confer structural stability to the stratum corneum. The stratum corneum lipids are composed primarily of ceramides, cholesterol, and fatty acids that are assembled into multi-lamellar bilayers. This unusual extracellular matrix of lipid bilayers serves the primary barrier function of the stratum corneum. The layer of lipids immediately adjacent to each corneocyte is covalently bound to the corneocyte and is important in maintaining barrier function. The stratum corneum is continuously desquamated, with a renewal period of 2–3 weeks. It is actively repaired by cellular secretion of lamellar bodies following the disruption of its barrier properties or other environmental insults [169]. Due to its structural heterogeneity, solute transport in stratum corneum lipid bilayers is highly anisotropic and size dependent, and that is why spatial variations in solute partition and diffusion coefficients are often observed [170].

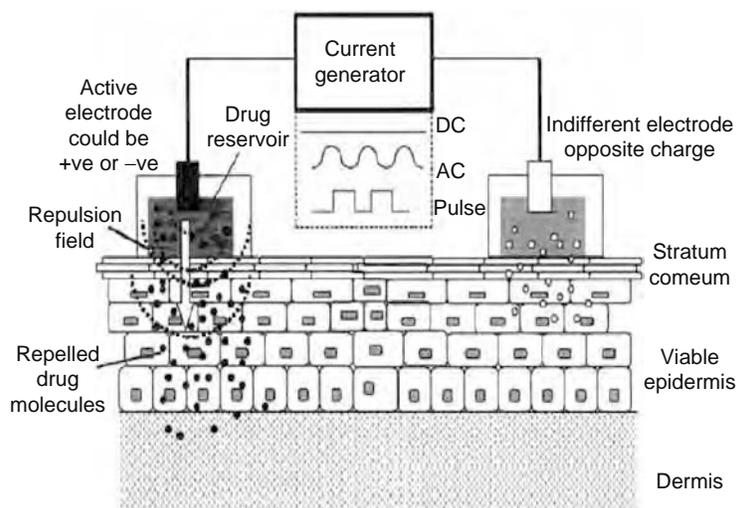

Just below stratum corneum, we can find the epidermis, a viable tissue devoid of blood vessels 50–100  $\mu\text{m}$  thick. The inner skin layer is represented by the dermis (1–2 mm thick) containing capillary loops able to take up transdermally administered drugs for systemic distribution [164]. On the basis of its morphology, in principle, drug penetration through skin can take place through sweat glands, hair follicles, and transepidermally [171,172]. However, the contribution of follicles is hard to be quantified (in human skin, their contribution is negligible [172]) as their number per unit area is not equal for the different body parts both in humans and animals). Undoubtedly, based on the surface area available to permeation, the diffusion mechanism through stratum corneum is the most relevant one and that is why stratum corneum characteristics, often, discriminate between drugs that can take or cannot take advantage from a purely diffusive transdermal strategy.

The release of a therapeutic agent from a formulation applied to the skin surface and its transport to the systemic circulation is a multistep process involving (a) dissolution within and release from the formulation, (b) partitioning into the stratum corneum (SC), (c) diffusion through the SC, principally via a lipidic intercellular pathway (i.e., the rate-limiting step for most compounds), (d) partitioning from the SC into the aqueous viable epidermis, (e) diffusion through the viable epidermis and into the upper dermis, and (f) uptake into the local capillary network and eventually the systemic circulation [173]. Therefore, an ideal drug candidate would have sufficient lipophilicity to partition into the SC, but also sufficient hydrophilicity to enable the second partitioning step into the viable epidermis and eventually the systemic circulation.

Transdermal patches can be classified into two categories on the basis of their design: reservoir-type and matrix-type patches [164]. A reservoir-type patch consists of four major components: the reservoir, where drug is hosted in a solution or in a gel, the rate-controlling membrane, the adhesive layer, and the backing. Drug release occurs due to drug permeation through the membrane and the adhesive layer to get skin surface. Typically, the reservoir contains also an enhancer, a chemical compound that diffuses through the membrane and the adhesive layer penetrates into skin improving its permeability to drug. A little variation of the reservoir-type patch is represented by the multi-laminate design, where drug is dispersed/dissolved in a solid polymer matrix [174]. By contrast, matrix-type patches, which were introduced after reservoir-type patches, combine drug, adhesive and patch backing into a simpler design that does not involve a rate-controlling membrane. Accordingly, skin permeability usually governs the rate of drug delivery. Although these patches are easier to fabricate, they have limited flexibility in their design compared with reservoir-type patches that also offer the advantage of higher formulation flexibility and tighter control over delivery rates. Obviously, reservoir-type patches usually involve greater design complexity. While reservoir-type patches can provide a constancy of drug release rate, which means that the device can supply a constant amount of drug per unit time, which is not achievable in matrix-type patches. On the contrary, however, reservoir-type patches can have an initial burst of drug release. As membrane plays a fundamental role in reservoir-type patches, it must satisfy some requirements. In particular, a drug diffusion coefficient ranging from about  $10^{-7}$  to  $10^{-9}$   $\text{cm}^2/\text{s}$ , the possibility of being fabricated in form of thin film, a low solubility for the drug, the property of being soft well above shipping temperatures and an elastic modulus about 1000–1 MPa constitute fundamental prerequisites. For example, polyethylene, ethylene vinyl acetate, and polypropylene films match the above-mentioned requirements [174]. In general, however, ethylene vinyl acetate films represent the best candidates for these applications as vinyl acetate content can be modified to tune membrane permeability in relation to drug. In addition, membrane thickness, ethylene components crystallinity, and domain structure are other important variables to properly design release rate characteristics. For what concerns adhesives, they must be very permeable to both drug and enhancers as drug release rate is demanded only to membrane.

### 15.5.2 MEMBRANES FOR PHYSICALLY ENHANCED DELIVERY SYSTEMS

While chemical enhancers can be a successful tool for the improvement of small drug permeability through skin, for big molecules other strategies have to be undertaken. Indeed, proteins and peptides transdermal administration requires the use of

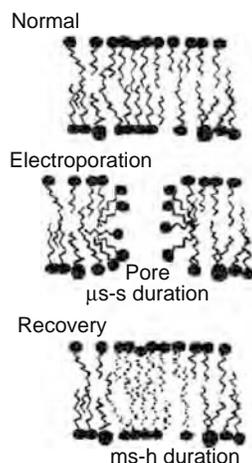

**FIGURE 15.14** Iontophoretic delivery devices basic design. Drug is placed on the skin under the active electrode, with the indifferent electrode positioned elsewhere on the body, and a current ( $<0.5$  mA) passed between the two electrodes effectively repelling drug away from the active electrode and into the skin. (From Cross, S.E. and Roberts, M.S., *Curr. Drug Deliv.*, 1, 81, 2004. With permission.)

physical methods to enhance permeability. Basically, these methods comprehend electrically based techniques (iontophoresis, electroporation, ultrasound, and photomechanical wave), structure-based techniques (microneedles), and velocity-based techniques (jet-propulsion) [163]. Although a detailed description of all these techniques is out of the scope of this section, some details on electrically based systems can be useful in the light of membrane applications in the delivery field.

Iontophoresis was initially developed to facilitate the delivery of ionized solutes, with inherently low partition coefficients due to their charged state, across tissue membranes. The technique involves the application of a small electric current (usually  $0.5 \text{ mA/cm}^2$ ) to a drug reservoir on the surface of the skin, with the same charged electrode as the solute of interest placed together to produce a repulsion effect that effectively drives solute molecules away from the electrode and into the skin [175] (Figure 15.14). The effect of simple electrorepulsion is known to be one of the main mechanisms by which iontophoresis produces its enhancement effects, although other factors such as a permeability increase of the stratum corneum due to an electric current flow, and electroosmosis of uncharged and larger water-soluble molecules can play an important role [176]. If iontophoresis proved to be successful for small molecular weight drugs ( $\text{MW} < 500$ ) [163,175], encouraging results can also be achieved for macromolecules and proteins. At this purpose, we can mention calcitonin (salmon) [177], corticotrophin-releasing hormone [178], delta sleep-inducing peptide [179], dextran sulphate [180], insulin [181], growth hormone-releasing factor [182], leuprolide acetate [183], leutenizing hormone-releasing hormone [184], neutral thyrotrophin-releasing hormone [185], oligonucleotides [186], parathyroid hormone [187], and vasopressin [188].

Electroporation is a technique that was initially developed for transmembrane delivery of macromolecules in isolated cells in culture systems and then expanded to intracellular delivery *in vivo* [189]. The process involves the application of large transmembrane voltages caused by electrical pulses ( $10 \mu\text{s}$  to  $100 \text{ ms}$ ), which probably cause the formation of transient pores (Figure 15.15) in the membrane that subsequently allow the passage of macromolecules from the outside of the cell to the intracellular space via a combination of possible processes including diffusion, local electrophoresis, and electroosmosis [190]. The application of electroporation to skin descends from the theory that the intercellular lipid bilayers of the skin should behave like those of cell membranes and be susceptible to pore formation following high-voltage electrical pulsing [191] (Figure 15.15). The work of Prausnitz and coworkers demonstrates the effectiveness of electroporation in transdermal drug delivery [164]. While the electrical resistance of the skin is reported to decrease as much as three orders of magnitude within microseconds of administration of an electrical pulse [192], skin permeability to drugs is also reported to increase by several orders of magnitude. This is mainly attributed to electrophoretic movement and diffusion through the newly created aqueous pathways [193] (Figure 15.15). *In vitro* experiments proved the increase in transdermal penetration up to  $10^4$ -fold not only for small molecular weight drugs, but also for bigger drugs such as leutenizing hormone-releasing hormone [194], insulin [195], and oligonucleotides [196].

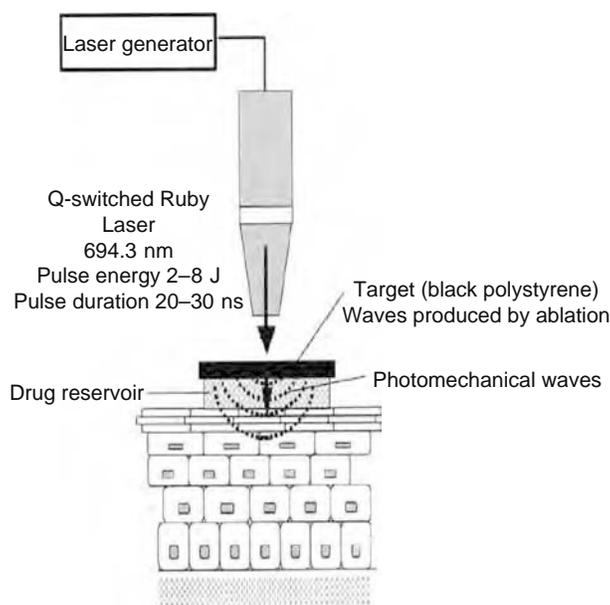

Ultrasound (or sonophoresis) is a technology more traditionally associated with the fields of physiotherapy, sports medicine, and medical imaging rather than transdermal drug delivery. Compared to physiotherapy, where high-frequency energy (1 MHz) is used, in transdermal drug delivery low-frequency energy (20 kHz region) is applied across the skin. Cavitation, the acoustically induced formation and oscillation of gas bubbles formed because of the mechanical energy supplied, is the most probable

**FIGURE 15.15** Hypothetical bilayer poration model. Pores are hypothesized to form in the intercellular bilayers via momentary realignment of lipids that recover their original position at various times after the electrical pulse. (From Cross, S.E. and Roberts, M.S., *Curr. Drug Deliv.*, 1, 81, 2004. With permission.)

explanation for skin permeability increase [197]. Indeed, bubbles presence and movement produce defects large enough to facilitate the passage of macromolecules through the stratum corneum bilayers. Recent studies demonstrate an increase of 2.6–15-fold of the estradiol, naphthol, aldosterone, lidocaine, and testosterone diffusion coefficient due to ultrasound.

Photomechanical waves (PWs) (also known as laser-generated stress waves) are the pressure pulses produced by ablation of a material target (polystyrene) by Q-switched or mode-locked lasers (Figure 15.16). Although the mechanisms by which PWs increase the permeability of the stratum corneum are not entirely clear, microscopic studies have indicated that the energy supplied promotes to the formation of transient channels through the stratum corneum. The PW delivery of insulin through the skin of diabetic rats was shown to cause reductions in blood glucose of around  $80\% \pm 3\%$ , and was maintained below 200 mg/dL for more than 3 h. The largest molecule that has been reported to be delivered through rat skin to date has been 40 kDa [163].

**FIGURE 15.16** Photomechanical wave delivery devices. A drug reservoir backed with a laser target material (e.g., black polystyrene) is placed on the skin. Laser-induced photomechanical waves are supposed to increase the permeability of the stratum corneum allowing the facilitated passage of drug molecules from the reservoir into the skin. ## 15.6 IMPLANTABLE DELIVERY SYSTEMS

Implants represent an important witnessing of the fruitful and necessary interaction among different competences typical of engineers, chemists, biologists, and medical doctors. Indeed, if on one hand human mind likes to subdivide and classify knowledge into different sectors (probably in the attempt of getting a simpler management of the complexity of the whole frame) and this gives origin to different professional figures, on the other hand the need for solving more and more complex problems requires the inverse process consisting knowledge sector merging. Accordingly, today, for example, chemical engineers cooperate with chemists and medical doctors to improve therapeutic reliability and the effectiveness of many delivery systems among which implants [198]. This delivery strategy, indeed, preliminary requires careful evaluation of the biocompatibility, defined as the property of a defined substance not to produce any toxic, injurious, or immunological response in living tissue [199]. Only on this basis it is possible to design a successful implantable delivery device that is able to work properly in the long-term period also. Accordingly, it is evident that the importance of the implant coating membrane assumes the role of mediator between the surrounding living tissues and the implants itself. A good implant performance implies a negligible foreign body response, i.e., a good biocompatibility.

Basically, immune response acts by two complementary pathways known as innate and specific immunity. Innate immunity comprises a set of defences not requiring recognition of foreign substances such as defensins, natural antibiotic proteins expressed in the gut and providing nonspecific protection from pathogens. Innate response can represent a serious problem for what concerns biomaterial implantation [199]. Specific immunity, on the contrary, is expressed by humoral and cell-mediated actions. Humoral immunity, devoted to destroy extracellular foreign substances, implies the recognition of a foreign substance (antigen) by antigen-specific B-lymphocytes and the following production of antigen-specific antibodies that coat the antigen (phagocytosis). Cell-mediated immunity, aimed to eliminate intracellular foreign substances (e.g., viruses), consists in the infected cell lysis by cytotoxic T-lymphocytes or in the elimination of intracellular microbes from infected macrophage because of cytokines produced by helper T-lymphocytes. Also cell-mediated immunity can cause problems for what concerns chronic response to implant [199].

In addition to a deep knowledge of immune response mechanisms, a reliable designing of implants needs to consider also timescale of the immune response. Indeed, there are three major timescales of the immune response: hyperacute, acute, and chronic. While hyperacute response, typically connected to innate immunity, develops on the timescale of seconds to minutes, acute response is humoral mediated and occurs on the order of weeks, its intensity and appearance being highly dependent on whether exposure to antigen is the first exposure or a repeated exposure. Finally, chronic response is cell mediated and occurs in the order of months to years.

As soon as an implant is put in its working site, the surrounding living tissue reacts (acute phase). If a consistent chemical or physical irritation takes place (as in the case of moving implants), a chronic inflammatory response occurs [200]. In the opposite case, on the contrary, a normal foreign body response develops and the implant is surrounded by a three-layer membrane [201]. The first stratum comprises macrophages and foreign body giant cell formations whose secretions give origin to the second layer, a dense and fibrous tissue 30–100  $\mu\text{m}$  thick. Finally, the third stratum is composed by highly vascularized tissue (granulation tissue). As this coating tends to be very stable and poorly permeable with respect to most chemical species, it is clear that its formation, de facto, prevents any kind of delivery from the implant to the surrounding living tissues.

Leoni [12,202], leading an interesting study on in vivo biocompatibility, observes different body responses in relation to the materials used and the site of implantation (rats). Silicon membrane (control) and PEG-modified silicon membrane were implanted in rat subcutis for 17 days and was then retrieved for analysis of body response. At gross examination, the tissue surrounding the samples differs mainly in the degree of vascularization. Indeed, very few blood vessels surround the control, while a rich network is present in the proximity of PEG-modified implants. In addition, histologic examination clearly reveals that PEG-modified samples have no sign of infiltration and the tissue has the characteristic structure and composition of the tissue found at the site of implantation. In another experiment, biocapsules were implanted in the rat abdominal wall and the omentum, and they were retrieved after 15 days of implantation. Different host response develops at the two sites of implantation. In the first case, a dense fibrotic tissue, consisting of collagen fibers, with parallel orientation and very poor vascularization is detected. On the contrary, no gross abnormalities of color or consistency are observed in the tissue surrounding omental pouch implants. The membrane surface appears to be free of tissue, while blood vessels are in its proximity. Microscopic analysis of the tissue reveals a nonuniform structure, with prevalence of large round cells typical of adipose tissue and loose connective tissue matrix, characterized by short collagen fibers randomly oriented. In both cases, no signs of infiltration are present.

A possible technique adopted to prevent fibrous capsule formation around the implant is the addition of a tissue intermediary [203,204]. Indeed, if this material has a continuous, interconnected, porous structure (pore diameter  $\geq 8$ –10  $\mu\text{m}$ ), macrophages are capable of invading structure voids. Consequently, vascularized tissue can grow in the implant and the foreign body response is avoided as this porous structure is able to mimic extracellular matrix. The first example of intermediary tissue use concerns the coating of an implanted catheter by means of a silicone rubber cage [205]. Typically,

swollen hydrogels, for their rheological properties and water content resembling those of soft tissues, are good candidate to act as intermediary membranes [198]. In particular, poly(2-hydroxyethyl methacrylate) (HEMA) hydrogels can be easily synthesized into macroporous sponge-like materials.

### 15.6.1 MEMBRANES FOR PASSIVE IMPLANTS

Implantable delivery systems can be classified as passive, biodegradable (bioerodable), and active [198]. In passive implants, drug release kinetics is controlled by drug diffusion through a nondegradable membrane that is usually constituted by silicone and poly(ethylene-co-vinyl acetate), polyacrylates. Indeed, membrane coats an active core represented by solid drug, drug solution, or dispersion. By properly choosing membrane thickness and permeability, release kinetics can be controlled and properly designed for a specific therapeutic target. For example, Norplant, an implantable 5 year contraceptive (developed by the International Committee for Contraception Research of Population Council), is based on this passive strategy for the long-term release of levonorgesterol (LNG) [174]. The first version of Norplant is a capsule system constituted by an LNG crystals core encapsulated by Silastic polymer (polydimethylsiloxane). An updated version consists in a Silastic matrix (containing LNG microcrystals) coated by an external membrane. Both the configurations yield an approximately constant release rate for about 15 months even if the first approach yields an initial nonconstant rate because of the nature of the drug present in the capsule. Indeed, if at the beginning drug transport is mainly ruled by LNG diffusion through membrane, for longer time, LNG dissolution is the rate determining step as slow water penetration transform the solid drug core into drug dispersion.

Alzet pumps (laboratory animal applications) and Duros (human applications) implants represent interesting examples of passive implants based on osmotic pressure [206]. Alzet device is a cylindrical structure composed by three main concentric parts: drug reservoir (the innermost part), osmotic agent, and semipermeable membrane (the outermost part). Drug reservoir is moulded from a flexible synthetic hydrocarbon elastomeric membrane carrying, in the upper part, an orifice for drug delivery. Obviously, the elastomeric wall is impermeable to water and drug to impede drug migration into the osmotic agent and vice versa. Sodium chloride is the osmotic agent filling the osmotic sector surrounding the drug reservoir. A cellulose ester blend constitutes the rigid semipermeable external membrane. The orifice end is equipped by a flow moderator (21 ga stainless steel tube) to reduce passive diffusion and convective losses. As soon as the device is put in contact with an aqueous external environment, the osmotic sector imbibes water, expands, and causes the shrinking of the flexible drug reservoir. Consequently, the release rate of Alzet pump depends on the water flux crossing the semipermeable membrane as predicted by Equation 15.35. It, therefore, clears the paramount importance of the semipermeable membrane that is, ultimately, the real heart of the whole system. On the contrary, except for very viscous or nonhomogeneous suspensions, the characteristics of the drug formulation do not affect the delivery profile. Typically, Alzet pumps deliver at fixed rate between 0.25 and 10  $\mu\text{L}/\text{h}$  for 1 day to 4 weeks. They are commonly implanted subcutaneously or intraperitoneally, although intracerebral, intravenous, and intra-arterial delivery has been used. Anesthetics, antibiotics, growth factors, hormones, and neurotransmitters are some examples of drugs that can be released by means of Alzet pumps. Duros implant is made up of a titanium alloy cylinder capped on one end by a rate-controlling, semipermeable membrane and on the other end by a diffusion moderator (orifice) for drug delivery [206]. Internally, this implant is equipped by a polymeric piston separating the osmotic chamber from drug reservoir. Semipermeable membrane can be made up of cellulose esters, polyamides, or polyurethane materials, which remain chemically stable under physiological conditions. The osmotic chamber contains sodium chloride (>50% wt) (although other solutes can be used) and gelling polymers, such as polyvinylpyrrolidone and sodium carboxymethylcellulose. Upon contact with an aqueous environment, water diffuses through semipermeable membrane, fills the osmotic chamber, and provokes forward piston movement that leads to drug delivery from orifice. Depending on semipermeable membrane characteristics, Duros implant can ensure drug release from 1 month (release rate 4.5  $\mu\text{L}/\text{day}$ ) to 1 year (release rate 0.25  $\mu\text{L}/\text{day}$ ). Due to its metallic nature, this system requires anesthesia to be implanted. Subcutaneous implantation is the preferred strategy, even though it is also adaptable to other sites of administration. Duros has been used to deliver leuprolide (palliative treatment of advanced prostate cancer), salmon calcitonin (osteoporosis treatment), and  $\alpha$ -interferon (antiviral and antiproliferative activity).

A particular kind of passive implants is represented by stents, rigid scaffolds that contribute to prevent artery re-occlusion after the mechanical removal of an atherosclerotic plaque by percutaneous trans-luminal angioplasty [207]. Although they can efficiently prevent early artery elastic recoil and late constrictive remodeling, two known events underlying restenosis [208], in 10%–30% of the cases, induce a pronounced intimal hyperplasia [209] characterized by exuberant proliferation of vascular smooth muscle cells (VSMCs), which contribute to occlude the treated vessel (restenosis) [210]. The pathobiologic events leading to artery restenosis start a few days after treatment [211] and are characterized by the proliferation of VSMC, normally present in a quiescent state in the media layer of arteries, in response to a variety of growth factors released at the site of artery treatment [212]. The process is completed by the migration of VSMC from the media to the intimal layer, followed by a further proliferation step and deposition of extracellular matrix proteins in the subendothelial space (intimal layer) giving origin to the so-called neo-intima [213–215]. In the light of this, membranes (stent coatings) can play a double important task as they can reduce foreign body response at the stent/tissue [216] interface and they can represent a mean for the release of antiproliferative substances at the site of stent implantation [210]. While nylon [217] and silicon [218] gave interesting

results for what concerns the insulation of the stent from surrounding tissues, many other materials have been considered for the in situ release of antiproliferative drugs [216]. Indeed, the choice of the coating material depends also on the drug to be incorporated. Both conventional (synthetic antiproliferative agents) and nonconventional (nucleic acid-based drugs) drugs can be considered [210]. While sirolimus [219] and paclitaxel [207] have been considered as conventional drugs, ribozymes, antisense oligonucleotides, DNA enzymes, and siRNAs, which represent the nonconventional approach [210]. Typically, polyurethane, polyglycol, silicon, polyvinylpyrrolidone-*co*-cellulose ester, and polyethylenglycol can be used for the drug eluting stent technology [220]. In addition, in the frame of ribozymes delivery, the use of thermoreversible gels (such as Pluronic) seems to be promising [221–223].

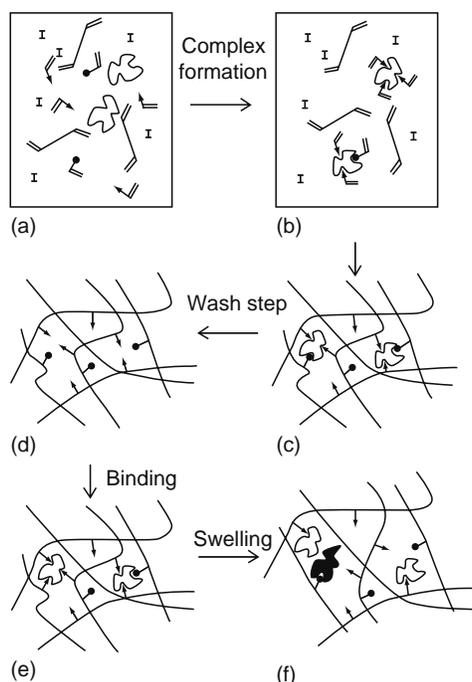

Apart from the possibility of an abrupt drug release due to membrane disruption when the reservoir-type implant is on site, the main disadvantage of passive implants consists surgical procedure required for their removal. Biodegradable/bioerodable polymers represent a possibility to overcome this problem as they are characterized by bonds that can be hydrolyzed or cloven by enzymes. Moreover, drug release is not only ruled by diffusion but also by polymer degradation kinetics. Finally, this strategy also allows to deliver high-molecular weight drugs, such as proteins whose diffusion in usual membranes is very low. Polyesters are typical biodegradable polymers and poly(lactic acid-*co*-glycolic acid) (PLGA) is one of the most used [198]. Indeed, PLGA hydrolysis leads to lactic acid and glycolic acid, which are natural cellular metabolites and, thus, are easily eliminated by the body. As the hydrolysis of lactic acid monomers is much faster than glycolic monomers, the rate of PLGA degradation can be controlled by simply playing on the copolymer ratio. While PLGA undergoes bulk degradation, poly-anhydrides are subject to surface erosion [57,224], an important advantage in implant designing. Indeed, in the case of surface erosion, system integrity is maintained for the lifetime of the device and drug release kinetics is more uniform. For example, poly(bis(p-carboxyphenoxy)propane-*co*-sebacic acid) is used for implants in local taxol delivery after an excised brain tumor [225]. As surface-eroding polymers exhibit a bigger tendency to degrade with respect to bulk-eroding polymers, drug release duration can represent a drawback for surface eroding polymers. This problem can be overcome by creating a composite release system of polyanhydride coated by a polylactic acid shell as demonstrated by Goeperich [224].

### 15.6.2 MEMBRANES FOR ACTIVE IMPLANTS

While passive and biodegradable implants fit very well a zero-order release demand, they cannot satisfy more complex release rate behaviors. Indeed, as in the case of diabetic patients, insulin release must be ruled by blood glucose concentration and it is well known that it can vary consistently during the circadian loop. Accordingly, an active implant needs to be able to adapt the release rate on the basis of an external, and physiological stimulus, and in this consists its “active” characteristic. Although no completely automated active implants have been yet reported [226], some interesting examples exist. Indeed, microfabrication technology allows developing active implantable microfluidic devices that incorporate micropumps, valves, and flow channels to deliver liquid solutions [226]. One of the key components in those devices is the miniature fluid-dispensing system (micropump). Various pumping methods are available, including electroosmotic pumping for ionic fluids, positive displacement pumps that use piezoelectric components, and pneumatic, bubble, or surface-tension pumps that rely on moving gas-liquid interfaces to displace fluids [227]. Another possibility is represented by the drug array implant, a solid-state silicon microchip for controlled release of single or multiple chemical substances on demand [228]. The release mechanism relies on the electrochemical dissolution of thin anode gold membranes covering microreservoirs containing chemicals in solid, liquid, or gel form. A sequential microfabrication process including photolithography, chemical vapor deposition, electron beam evaporation and reactive ion etching has been used to create 34 microreservoirs on the chip, each covered by a thin gold membrane functioning as the anodes. The gold membrane is dissolved upon application of a desired voltage and this leads to drug release into the surrounding fluid. The possibility of individually controlling each reservoir allows the achievement of many complex release patterns.

## 15.7 FUTURE TRENDS

Previous sections illustrate some different applications of membranes in the delivery field with particular attention to oral, transdermal, and implantable delivery systems. It reports that, basically, membranes are required to modulate mass transport or insulate the delivery system from the surrounding tissues to prevent foreign body response. In most situations, both these tasks take place only on a passive basis in the sense that the delivery system behavior is not influenced by external, physiological stimuli. Nevertheless, it is clear that the new generation of delivery systems (regardless the administration route) will be based on an active basis so that the system is able to autonomously react to external stimuli, such as the concentration of a fixed analyte [229]. This is the reason why smart and biomimetic materials are becoming more and more attractive for the delivery field. Indeed, while the term “smart” is attributed to materials having property of shape memory (these materials, e.g., expand or constrict to external stimuli such as pH, light, or pressure), “biomimetic” refers to materials able to mimic or elicit biological function [198]. The synergic effect of these materials and nano-microtechnologies will determine the characteristics and properties of the future delivery systems [230,231] where membranes will surely play a fundamental role.

**FIGURE 15.17** Imprinting process scheme. (a) Solution mixture of template, functional monomer(s) (ending with triangles and circles), cross-linking monomer, solvent, and initiator (I). (b) The pre-polymerization complex is formed by means of covalent or non-covalent bonds. (c) Cross-linking yields the network formation. (d) Removal of the original template by a proper washing. (e) Rebinding of template. (f) In weakly cross-linked systems, macromolecular chain movements yield areas of differing affinity and specificity (filled molecule is isomer of template). ### 15.7.1 MOLECULARLY IMPRINTED MEMBRANES

Many of the future drug delivery systems will be based on intelligent gels able to autonomously react to external stimuli to modulate drug release in response to pH, temperature, ionic strength, electric field, or specific analyte concentration differences. Accordingly, the realization of a precise macromolecular chemical network able to recognize target molecules from an ensemble of closely related molecules is of paramount importance. Molecular imprinting is a possible strategy allowing the achievement of the above-mentioned task [231]. This technique (Figure 15.17) implies the formation of a pre-polymerization complex between the template molecule and functional monomers or functional oligomers (or polymers) [233] with specific chemical structures designed to interact with the template either by covalent [234], non-covalent chemistry (self-assembly), or both [235,236]. Once the pre-polymerization complex is formed, the polymerization reaction occurs in the presence of a cross-linking monomer or chemical cross-linking methods and an appropriate solvent controls the overall polymer morphology and network structure. Template removal leads to a heteropolymer matrix able to specifically recognize template molecules. In the light of this, molecular imprinting can be seen as a technique allowing the stabilization of a particular arrangement of chemical groups (triangle and circle ending chains in Figure 15.17) by means of a polymer network. Obviously, the properties of molecular imprinted network (MIP) depend on monomer chemistry (anionic, cationic, neutral, and amphiphilic), on the association interactions between monomers and pendant group, on solvent and on the amount of comonomers present in the mixture from which the structure is formed. In addition, MIP recognizing behavior results from the synergism between shape-specific cavities matching the template molecule and chemical groups orientated to get multiple complexation points (binding sites) with the template molecule. Finally, MIP are characterized by a bimodal distribution of binding sites, meaning that a small number of high-affinity sites correspond a large number of low-affinity sites. In particular, non-covalent MIP will be characterized by a heterogeneous population of binding sites with changing affinity and selectivity [237]. One major problem of MIP depends on the possibility that phenomena such as polymer swelling and macromolecular chains relaxation induce a distortion of the shape-specific cavities leading to an incorrect three-dimensional orientation of complexation points facing in the cavities. This, in turn, reflects in reduced MIP selectivity and specificity. This problem, particularly important for structures undergoing considerable swelling such as gels, can be matched by increasing cross-linking agent in order to get a reduction of the average molecular weight between cross-links this reflecting into a more rigid structure. In particular, Peppas and coworkers [232] suggest to realize a network structure characterized by an inhomogeneous spatial distribution of cross-links so that higher cross-linked regions are embedded in lower cross-linked continuum matrix. Only higher cross-linked zones contain

an effective imprinting structure and a proper rigidity to produce adequate specificity (areas or patches of recognition). In addition, the structure of these two regions allows a better template diffusion, reflecting into higher rebinding percentage with respect to more traditional, one-phase (fully cross-linked) gels. On the other hand, of course, this approach suffers a reduced number of recognizing sites per gel unit mass of volume. An alternative to this strategy is represented by a post cross-linking reaction after gel and imprint formation. Excess functional monomers on opposite macromolecular chains or monomers subsequently added allow the post cross-linking process. In low cross-linked gels, the idea of increasing the molecular mass (linear size) of functional monomers should reduce the loss of active binding sites due to network size fluctuations induced, for instance, by swelling. Indeed, short functional monomers cannot conserve their correct spatial disposition upon mesh enlarging. Irrespective of the low or high cross-linking degree, depending on the template size, there is an optimal value for the network cross-link density.

For biological applications, non-covalent interactions with template molecules are preferred to get an easy binding/nonbinding process. Indeed, in this field, the need for strong template removal conditions would make molecular imprinting useless. Nevertheless, due to the weak nature of non-covalent bond, stable binding and recognition require an increased number of interactions with respect to the case of covalent bond (typically, a covalent bond is 1–3 order of magnitude stronger than a non-covalent one) [237]. The quality of the receptor mechanism of imprinted polymers can be evaluated by means of different parameters. Binding affinity, a measure of how well the template molecule is attracted to the binding site, selectivity, the ability to differentiate between the template and other molecules, and the binding capacity, the maximum amount of template bound per mass or volume of polymer, represent the most important. Less important parameters are binding or imprinting ratios representing the ratio of recognitive network template bound compared to control network. Binding affinity can be quantified by means of the receptor–template dissociation constant  $K_d$ , that can be defined starting from the typical macromolecular–template complex  $[MT]$  reaction [237]:

where

$[M]$  is the macromolecular binding sites concentration

$[T]$  is the template concentration

$k_f$  and  $k_r$  represent the forward and reverse rate constants, respectively

The equilibrium binding constant or association constant,  $K_a$ , and the equilibrium dissociation constant,  $K_d$ , are expressed by

$$K_a = \frac{k_f}{k_r} = \frac{1}{K_d} = \frac{[MT]}{[M][T]} \quad (15.86)$$

Equation 15.86 simply descends from the equilibrium condition requiring that the forward reaction rate ( $R_f$ )

$$R_f = k_f[M][T] \quad (15.87)$$

equates the reverse one,  $R_r$ :

$$R_r = k_r[MT] \quad (15.88)$$

While low  $K_d$ , or high  $K_a$ , indicate a strong interaction between macromolecular binding sites and template molecules, high  $K_d$ , or low  $K_a$ , indicate the opposite situation. The ratio between the association ( $K_a$ ) (or dissociation,  $K_d$ ) constants characterizing templates differing in chemical functionality, orientation of chemical functionality, or physical size, defines the selectivity ( $\alpha$ ) of an imprinted network. Typically, for non-covalent imprinted polymers,  $\alpha$  ranges between 1.1 and 8 [234], and imprinted polymers with high association constants usually display high  $\alpha$  values.

On the basis of the above considerations, the applications of imprinted polymers in the pharmaceutical field are straightforward. Indeed, they can be profitably used both in responsive delivery systems and as biosensors. For example, HEMA-based polymers were imprinted to recognize hydrocortisone as template molecule [238]. Once the template was removed, the imprinted network was loaded with testosterone, a molecule structurally similar to hydrocortisone. The release of testosterone performed in the presence or absence of hydrocortisone in solution was different showing a higher release rate when hydrocortisone was present. Indeed, the high-imprinted network binding affinity for hydrocortisone promoted testosterone detachment from binding sites and this reflected into an increased testosterone release rate. In addition, methacrylic acid (MAA) was used as functional monomer for the controlled release of propranolol ( $\beta$ -blocker), tetracycline, and sulfasalazine (prodrug) [237]. Interestingly, MAA also proved to be effective in the enantioselective-controlled release, minimizing the

transport of a diastomer, the undesirable isomer, while allowing the transport of a eutomer, the isomer of interest [239]. Imprinted polymers have also shown to be profitably employed as biosensors in the detection of nandrolone [240], okadaic acid [241], caffeine [242] and paracetamol [243]. Another interesting application of imprinted polymers is about the optical sensors platform. Indeed, a recent nanoscale-fabricated optical sensor is based on the variation of quantum dots photoluminescence due to template binding on an imprinted polymer membrane coating quantum dots [244].

### 15.7.2 MEMBRANES IN MICRO/NANOTECHNOLOGIES

It is well established that future delivery systems will be completely automated to provide a closed loop therapy [198,229,237,245]. This means that they will (i) monitor the physiological conditions inside the patient body and convert it to electronic signals by means of physical and chemical transducers; (ii) receive the electronic signals, analyze them, and make proper control regulations by means of microcontrollers; (iii) release the appropriate amount of drugs by means of micro-actuators. For this reason, they can be defined as lab-on-a-chip [226,237]. To achieve this target, different components (microactuators, micropumps, microvalves, flow regulators, microsensors, and control electronics) have to be integrated, characterized and assembled on a very small surface. A possible assembling example should not differ too much from an array of microreservoirs etched into a silicon matrix [227,246]. Each reservoir, covered with an individual gold membrane, can be filled with solid or liquid drug. Drug release occurs by gold membrane electrochemically dissolution. ChipRx Company, in Ohio, is developing an integrated, self-regulating responsive therapeutic device of cylindrical shape devoted to release various drugs, e.g., insulin [247]. An external biocompatible permeable membrane surrounds an artificial muscle membrane inside which batteries, control circuit, biosensor, and drug reservoir are housed. When the sensor reveals a variation of the physiological levels of metabolites (i.e., glucose), a signal is sent from the sensor to the batteries, which emit an electrical charge causing the opening of a responsive material that allows the release of the desired therapeutic agent (e.g., insulin) from a reservoir. Once metabolites levels return to normal, the sensor stops the release of electrical charge from the battery, closing the reservoir and preventing the release of more drug. Interestingly, Langer and coworkers proposed a resorbable polymeric microchip device for multipulse drug delivery [248].

Due to a wide variety of possible applications, it is now not easy to predict the exact effect of micro- and nanotechnologies on membranes. However, it is reasonable to suppose that these technologies, for example, will allow producing membranes characterized by an extremely controlled porosity regardless the constituting material. Indeed, it will be possible to drill the membrane getting cylindrical holes characterized by very small diameters and with the desired diameter distribution (mono-dispersed, for example) and spatial collocation. In addition, very thin membranes with very small tolerance on thickness could be produced and this will allow the stratification of many thin layers each one characterized by different properties. Accordingly, the resulting wafer could be very versatile its characteristics resulting from the combination of each layer properties. In turn, this could confer very peculiar behavior for what concerns, for example, mass transport, mechanical, and electrical properties.

## 15.8 CONCLUSIONS

The aim of the chapter is to illustrate and discuss membrane applications in the delivery field devoting particular care to the mechanisms ruling mass transport, make clear that membranes often play a key role as they are very versatile. Indeed, while they can be used to modulate drug mass flux to guarantee the desired release kinetics, they can also act as barriers separating an external environment from an internal environment as explained. Obviously, due to the great variety of applications, it was not possible to consider all of them, but I believe that the most significant have been shown. In addition, some of them, for the sake of brevity, could not be discussed. In particular, I am referring to the wide field of living cells encapsulation techniques used in tissue engineering [12,249]. In this case, interestingly, membranes are called to contemporaneously act as barrier and mass transport modulators. Indeed, they must protect living cells hosted in the microcapsule from the immune response of the hosting body where they are implanted to perform their action (e.g., insulin release in diabetic patients). Accordingly, membrane must be impermeable to immunoglobulins, big molecules devoted to the destruction of foreign bodies. Contemporarily, however, they must allow nutrients ( $\text{Na}^+$ ,  $\text{K}^+$ , oxygen, and glucose) permeation to feed encapsulated cells. Clearly, this is just a further example of the complexity of membrane actions and it underlines that a proper membrane designing is needed. A possible tool to match this goal is represented by mathematical modeling and this is the reason why the initial part of this chapter is devoted to describe release mechanisms, fundamental bases for getting a reliable mathematical model.

## 16.1 INTRODUCTION TO HYDROGELS

### 16.1.1 GENERAL PROPERTIES

Hydrogels are produced from cross-linked hydrophilic polymers to give three-dimensional mesh structures or networks. By appropriate choice of synthetic conditions, gels can be formed which are either able to hold therapeutic molecules entrapped within the mesh structure or to act as a gating barrier [1]. Immersed in an aqueous solution, these polymeric networks are capable of imbibing large amounts of water or biological fluids [2,3]. However, the internal cross-links prevent complete dissolution and constrain the degree of swelling and hence the release rate of solutes.

Hydrogels have been extensively studied for biomedical applications where their hydrophilic properties and high-water content allow good biocompatibility [4,5], and their soft structure is mechanically similar to that of natural tissue [6]. In addition to a general swelling phenomenon resulting from the balance between the thermodynamic effect of dilution and the opposing retractive force of polymer chain extension, hydrogels may also show swelling changes, which are a function of changes in the chemical composition of their external environment [7].

**TABLE 16.1**  
**Monomers Most Commonly Used in the Synthesis of Synthetic Hydrogels for Pharmaceutical Applications**

Monomer Abbreviation	Monomer
HEMA	Hydroxyethyl methacrylate
HEEMA	Hydroxyethoxyethyl methacrylate
HDEEMA	Hydroxydiethoxyethyl methacrylate
MEMA	Methoxyethyl methacrylate
MEEMA	Methoxyethoxyethyl methacrylate
MDEEMA	Methoxydiethoxyethyl methacrylate
EGDMA	Ethylene glycol dimethacrylate
NVP	<i>N</i> -Vinyl-2-pyrrolidone
NIPAAm	<i>N</i> -Isopropyl AAm
Vac	Vinyl acetate
AA	Acrylic acid
MAA MAA	HPMA <i>N</i> -(2-hydroxypropyl) methacrylamide
EG	Ethylene glycol
PEGA	PEG acrylate
PEGMA	PEG methacrylate
PEGDA	PEG diacrylate
PEGDMA	PEG dimethacrylate

### 16.1.2 MATERIALS OF CONSTRUCTION

Hydrogels have been produced using a range of backbone materials. These can be broadly divided into two categories. The first category is based on the cross-linking of preformed polymer chains e.g., dextran [8]; the second category involves building the gel by polymerizing a suitable mixture of monomers [4]. A summary of monomers that have been used for this purpose is given in Table 16.1.

Cross-linking preformed polymers offer potentially simpler coupling chemistry, and the ability to use chains of predefined molecular weights means that final gel properties are easier to predict. Conversely, synthesis of polymer gels directly from their constituent monomers allows considerably more flexibility in terms of the combination of pendant groups incorporated and can be expected to be cheaper. Gels containing charged groups, which show pH-responsive behavior and temperature-responsive gels incorporating poly(*N*-isopropylacrylamide) (PNIPAAm) are often produced in this way [9], although a number of naturally charged polymers, for e.g., alginate and hyaluronic acid can also be used to form pH-sensitive gels [10,11].

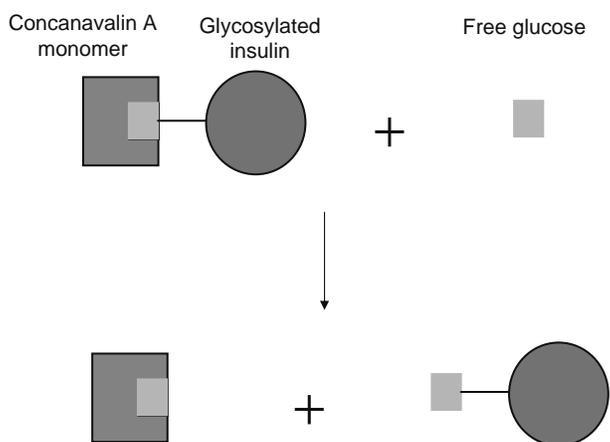

### 16.1.3 SYNTHESIS PROTOCOLS

The cross-linking methods used to produce pH-sensitive hydrogels can be either physical or chemical [2]. Physical methods include high-energy radiation and UV-irradiation [12]. Alternatively, emulsification methods [13] and free-radical polymerization [14] have been employed to chemically fabricate pH-sensitive hydrogels. The magnitude of the volume collapse arising from the pH response can easily be detected allowing these hydrogels also to be used for biosensors and permeation switches [15].

Recently, attention has been paid to new syntheses and applications of carbodiimides in hydrogels, allowing bioconjugation based on amide formation under very mild conditions between carboxylic acids and amines in aqueous and organic systems [16]. There are two advantages to using 1-ethyl-(3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) as the cross-linking agent for hydrogel preparation from carboxylated precursor. First, the reaction conditions are mild and easily controlled by the level of COOH group substitution. Second, EDC is not incorporated into the cross-linked structure leaving no potentially cytotoxic groups in the gel [17].

### 16.1.4 AREAS OF APPLICATION

The use of hydrogels has been explored in tissue engineering, drug delivery, biosensors, and biological actuator applications. This results from the ease with which physicochemical properties of the hydrogel can be modified by changing monomer structure, the degree of cross-linking, and the fabrication method [18–21]. In addition, their chemical stability can be varied to give both stable and biodegradable constructs with good biocompatibility [6].

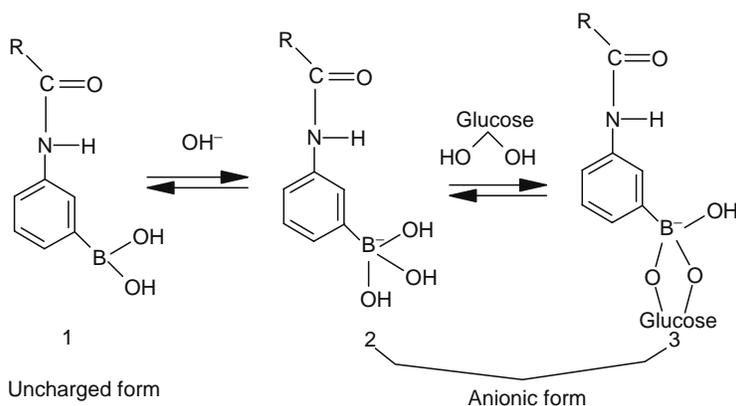

**FIGURE 16.1** (See color insert following page 588.) Displacement of ConA bound glycosylated insulin by free glucose.

In the area of responsive materials pH-sensitive hydrogels have been most frequently studied and have been used to develop a range of controlled release formulations for oral drug administration [22]. The functional mechanism of pH sensitivity is that small changes in pH can result in significant change in the mesh size of the gels' polymeric networks resulting from charge repulsion effects [23].

D-glucose-sensitive hydrogels have been examined for the development of self-regulated insulin delivery systems to act as an artificial pancreas that can administer the necessary amount of insulin in response to the blood glucose concentration [24]. Three approaches have been examined. The earliest reports are based on immobilized glucose oxidase in a pH-responsive hydrogel [25]. The second approach is based on the competitive displacements of affinity cross-links in bio-responsive hydrogels by D-glucose. Here the first systems that were studied used insulin chemically modified to introduce glucose moieties, which bind specifically to the lectin concanavalin A (ConA) [26,27]. In this approach, glycosylated insulin is competitively displaced from immobilized ConA by soluble glucose (Figure 16.1). To avoid problems associated with a derivatized form of insulin, ConA can be used to cause affinity gelation of a polymer containing terminal or pendant glucose moieties to form a responsive hydrogel [28,29].

A nonbiological route to fabricate glucose-sensitive hydrogels has also been developed using polymers having phenylboronic acid groups and polyol polymers, which form a gel through complex formation between the pendant phenylboronic acid and hydroxyl groups of glucose (Figure 16.2). Glucose can compete with polyol polymers for the borate cross-linkages, thus the cross-linking density of the gel decreases and the gel swells or transforms from the gel phase to release more drugs as the glucose concentration increases [30–32].

Owing to their structural similarity to the macromolecular-based components in the body (and their biocompatibility, permeability, and physical characteristics), hydrogels can also serve as a synthetic extracellular matrix (ECM) to organize cultured cells into a three-dimensional architecture and to present stimuli that direct the growth and formation of a desired tissue [33]. The balance between mechanical properties and controlled degradation of hydrogels mainly depends on the original

**FIGURE 16.2** Interaction between an immobilized boronic acid group and the vicinal diols of a glucose molecule. (From Kataoka, K., Miyazaki, H., Bunya, M., Okano, T., and Sakurai, Y., *J. Am. Chem. Soc.*, 120, 12694, 1998. With permission.)

rigidity of the polymer chains, the types of cross-linking molecules and the cross-linking density, and swelling as a result of hydrophilic/hydrophobic balance [34]. The ability to cast gels into thin membranes allows fabrication of support matrices with controllable mass-transfer resistances for both drug delivery and cell culture applications.

The development of responsive hydrogels for use in biosensors has been limited by the lack of accurate techniques to gauge their volume change in response to any stimulus. Recently, with the advent of sophisticated micro-fabrication facilities and new material technologies, diffractive and miniaturized optical gratings have been produced using hydrogels for biosensor applications [35]. Using hydrogel membranes in biosensors allow combination of biological receptor compounds (antibody, enzyme, nucleic acid, etc.) with the physical or physicochemical signal transduction required (e.g., optical, mass, electrochemical, or thermal). Ideally, these biosensors permit real-time observation of a specific biological event (e.g., antibody–antigen interaction) and allow the detection of a broad spectrum of analytes in complex sample mixtures. Furthermore, additional applications using immobilizing biocatalysts have been expected to act as biomimetic actuators giving surfaces with switchable hydrophobic–hydrophilic properties [36].

Hydrogels based on dextran have recently received specific attention due to their suitability for a variety of biotechnological and biomedical applications. Owing to their low tissue toxicity and high enzymatic degradability at desired sites, dextran hydrogels are increasingly seen as potential matrix systems for drug delivery [37] and controlled release of bioactive agents [38]. For dextran hydrogels targeted at colon-specific drug delivery, the drug is loaded into the hydrogel, which undergoes no or little release in the stomach and small intestine and is protected against digestion by enzymes [39].

Dextran hydrogels have been successfully applied in biosensors based on surface plasmon resonance. Carboxymethyl-dextran (CM-dextran) hydrogel was the original sensor surface developed for biomolecular interaction analysis and hence the most extensively studied and versatile. It has been used in a very wide range of interaction analyses including those between proteins, nucleic acids, and carbohydrates [40,41].

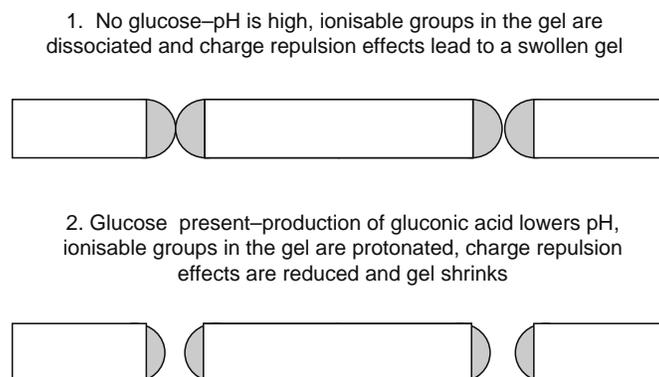

## 16.2 RESPONSIVE HYDROGEL MEMBRANES

Responsive membranes represent a specific subset of hydrogel applications. Responsive membranes ideally undergo rapid, reversible changes in microstructure. Small changes in the environment trigger changes at the macroscopic level leading to changes in mesh size or swelling ratio. Because these macroscopic changes are reversible, the system returns to its initial state after the triggering agent is removed [42].

Responsive membranes are attractive for drug delivery systems, as the delivery rate, chemical sensing, and triggering can be integrated and precisely controlled. Depending on the chemical composition of the gel, different internal and external stimuli (e.g., changes in pH, changes in specific solute concentration, application of a magnetic or electric field, variations in temperature, or ultrasound irradiation) may be used to trigger the swelling effect [43]. Once triggered, however, the rate of entrapped drug release is determined solely by the cross-linking ratio of the polymer network.

### 16.2.1 REACTIVE SYSTEMS

Reactive or catalytic systems are based on pH-responsive hydrogels where the chosen reaction generates a pH shift, which in turn leads to a swelling change in the hydrogel. This response can either be used to increase the internal mesh size to increase solute diffusivity in the gel phase for a diffusive membrane [44] or alternatively the gel can be used as a mechanical valve within the pores of a microporous membrane such that a convective flux may be turned on or off in response to analyte concentration (Figure 16.3) [45].

**FIGURE 16.3** Pore opening in a pH-sensitive gel containing glucose oxidase resulting from gel shrinkage.

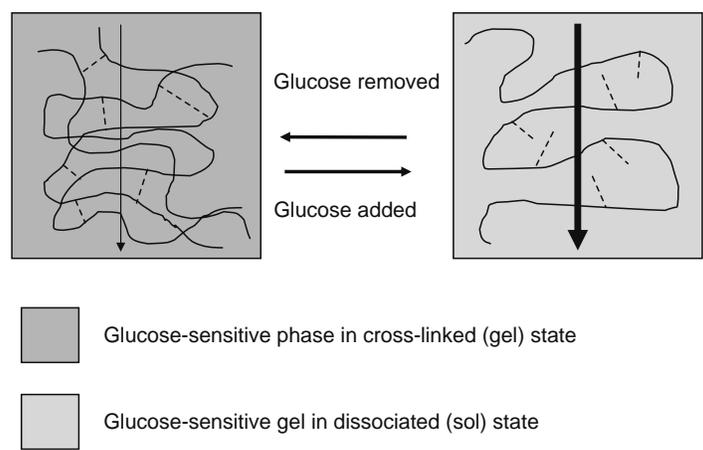

FIGURE 16.4 Schematic diagram showing the effect of competing glucose causing a gel to sol transition and increasing solute diffusion.

### 16.2.2 BINDING SYSTEMS

Cross-linked hydrogels can be formed which contain affinity cross-links between polymer-supported ligands and receptors [46]. Such gels can be based only on these biophysical interactions as described by Taylor et al. [28,29]. In these systems, displacement of affinity cross-links by soluble competitors ultimately leads to a gel/sol transition (Figure 16.4) requiring that the responsive phase be constrained between two diffusive membranes to prevent leakage while in the sol phase (Figure 16.5).

An alternative approach is to augment affinity cross-links with covalent cross-links at a specified density such that the total number of cross-links determines the permeability change and degree of swelling observed in the polymer when exposed to competing diffusible ligands [24,47,48]. In this case, the covalent coupling prevents dissolution of the gel and removes the need for an external diffusive layer (Figure 16.6).

In both types of binding systems competitive reduction of cross-link density will lead to an increased mesh size and hence increase solute diffusion. However, as this will inevitably be accompanied by some degree of gel swelling, these gels cannot be used to switch on convective solute flux as can be done with pH-sensitive gels, where both swelling and contraction effects can be generated.

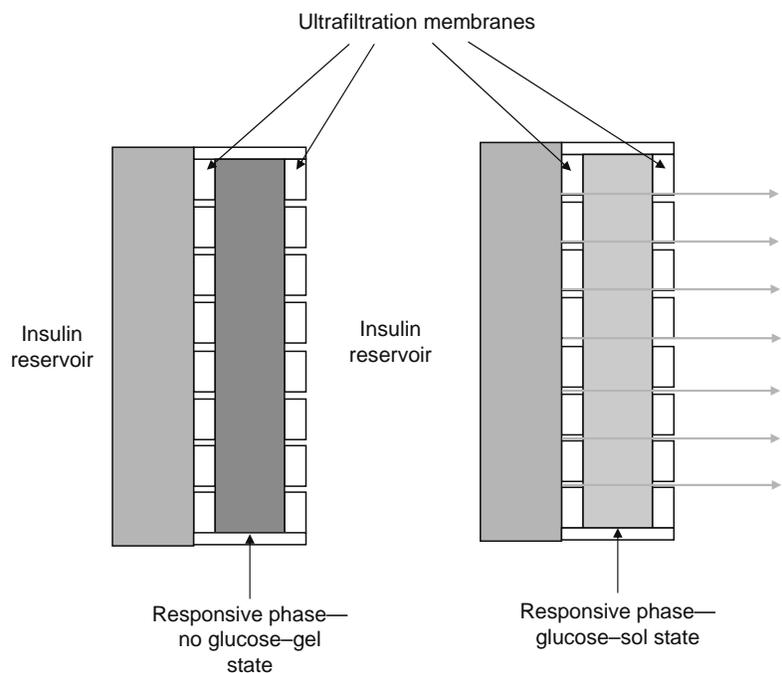

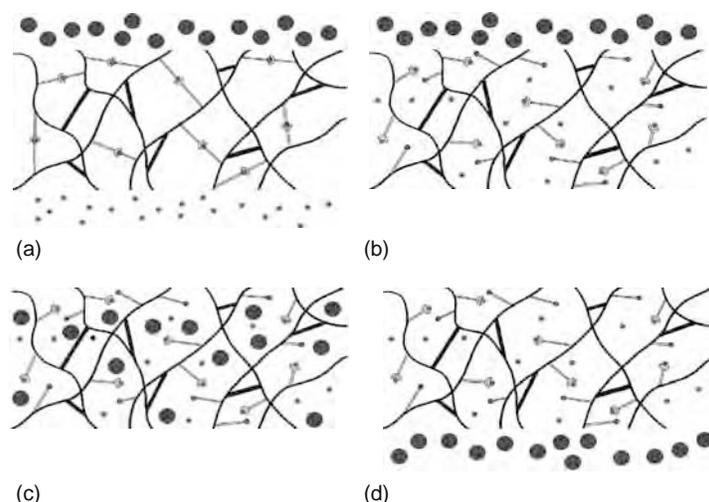

FIGURE 16.5 (See color insert following page 588.) Diagram showing the structural elements of a responsive sol/gel release system.

**FIGURE 16.6** (See color insert following page 588.) Mode of action of a glucose responsive hydrogel based on ligand–receptor interactions (bold lines denote covalent links). (a) Gel porosity reduced by affinity cross-links that exclude large molecules, e.g., insulin (blue), (b) glucose (red) diffuses in and competitively displaces affinity cross-links, (c) insulin is able to diffuse into the more highly porous gel, and (d) insulin diffuses through the gel providing the concentration gradient and glucose concentration is maintained.

## 16.3 MEMBRANE PREPARATION

### 16.3.1 COMPOSITE STRUCTURES

For responsive systems where changes in transport properties result from a sol/gel transition, the active components need to be retained by an ultrafiltration membrane to prevent loss of material while the responsive phase is in a sol state as shown in Figure 16.5. Hydrogels fabricated from ConA with glucose-containing polymer chains can be made to undergo sol–gel phase transformations depending on the glucose concentration in the environment. Because of the non-covalent cross-linking between glucose-containing polymer and ConA, individual free glucose molecules can compete with the polymer-attached glucose molecules and exchange with them as the external glucose molecules diffuse into the hydrogel. It has been shown that diffusion of insulin through the solution (sol) phase is faster than that through the hydrogel (gel) phase, and that insulin release can be controlled as a function of the glucose concentration in the environment [28,29,49–52]. In addition to the use of diffusive membranes to retain the polymer components, leakage can also be reduced by coupling the receptor protein to a larger polymer preparation, e.g., a carbopol [53].

### 16.3.2 DIRECT CASTING

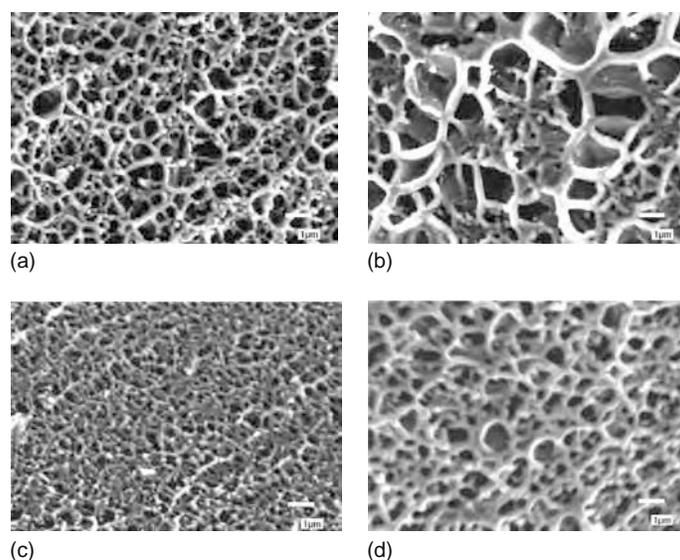

To remove the need for containment membranes, Tang et al. [54] cross-linked ConA with dextran to form a hydrogel which could be cast as a flat sheet membrane. This material was mechanically weak but could be reinforced using internal support gauze. In transport studies, membrane permeability showed a reversible change with the addition and removal of D-glucose and there was no evidence of component leakage from the gel (Figure 16.7). A similar material was developed which changed permeability in response to the coenzyme NAD [48].

### 16.3.3 PORE-FILLED SYSTEMS

To improve the mechanical properties of membranes based on soft gels, a number of groups have developed techniques for casting hydrogels within the pores of preformed microporous membranes (Figure 16.8) [55,56]. These composite membranes have been investigated for a range of applications including water softening [57], synthesis [58], nanofiltration [59], and fuel cells [56,60]. As the transport properties of these membranes will depend on the polymer phase within the pores, transport will still depend on cross-link density [61] and charge effects [62] as discussed below.

## 16.4 THEORETICAL DESCRIPTION

Effective modeling of hydrogel performance requires the effect of environmental changes on both the swelling ratio and mesh size of the gel to be determined. Models have been proposed to describe the effects of environmental changes on both neutral and charged hydrogel matrices where swelling changes result from charge repulsion or hydrophobic effects [4]. Models to

**FIGURE 16.7** SEM pictures showing structural changes in a dextran ConA hydrogel in response to glucose. describe the performance of affinity response systems, where swelling results from reversible changes in cross-link density have not previously been described, but can be formulated by combining predictions of affinity cross-link density using quantitative descriptions of binding interactions, with swelling theories developed for use with hydrogel polymers.

## 16.4.1 EQUILIBRIUM SWELLING THEORY

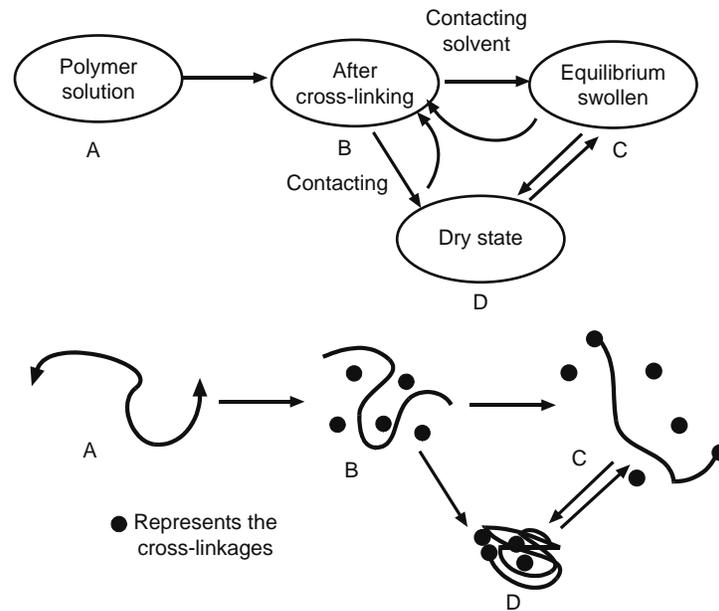

### 16.4.1.1 Neutral Gels

Neutral cross-linked hydrogels are commonly described in terms of the polymer volume fraction in the swollen and unswollen state and the number average molecular weight of the polymer chain between adjacent cross-links. The difference between polymer volume fractions can be determined from the swelling ratio of the gel (Figure 16.9) [63].

The equilibrium swelling theory of Flory and Rehner [64] assumes that the degree of swelling of an uncharged gel results from the effects of just two opposing forces: the thermodynamic effects of mixing tending to dilute the polymer component and the elastic constraints imposed by the force required to stretch the polymer chains. At equilibrium, these two forces are equal.

**FIGURE 16.8** Structure of a pore-filled membrane. A responsive hydrogel is incorporated into the pores of the substrate membrane to form a stable composite membrane.

**FIGURE 16.9** Schematic illustration of the different states of gels and their mesh chain conformations: A is the free mesh chain solution, B is the newly formed gel in the relaxed state, C is the equilibrium swollen state after contacting with solvent molecules, and D is the gel in the dried state. (From Huang, Y., Szleifer, I., and Peppas, N.A., *Macromolecules*, 35, 1373, 2002. With permission.)

Peppas and Merrill [65] modified the Flory–Rehner theory to describe the preparation of hydrogels in the presence of water to obtain the following relationship:

$$\frac{1}{\bar{M}_c} = \frac{2}{\bar{M}_n} \frac{\left(\frac{\bar{v}}{V_1}\right) \left[ \ln(1 - v_{2,s}) + V_{2,s} + x_1(v_{2,s})^2 \right]}{v_{2,r} \left[ \left(\frac{v_{2,s}}{v_{2,r}}\right)^{1/3} - 0.5 \left(\frac{v_{2,s}}{v_{2,r}}\right) \right]} \quad (16.1)$$

where

$\bar{M}_c$  is the number average molecular weight of the polymer chain between cross-links

$\bar{M}_n$  is the number average molecular weight of the polymer chain

$\bar{v}$  is the partial specific volume of the polymer

$V_1$  is the molar volume of water

$x_1$  is the Flory polymer-solvent interaction parameter

$v_{2,s}$  is the polymer fraction of the gel at equilibrium swelling

$v_{2,r}$  is the polymer fraction of the gel after gel formation

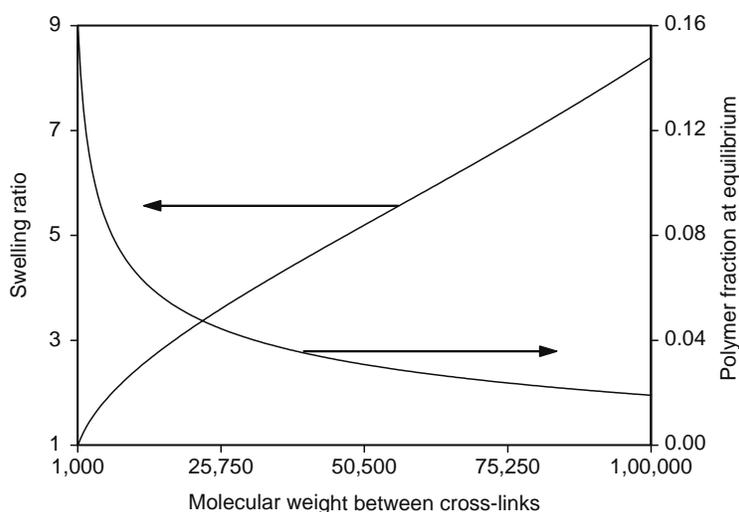

This relationship is commonly used to determine the cross-link density of a gel from experimentally determined swelling ratios, where the swelling ratio is given by

$$Q = \frac{v_{2,r}}{v_{2,s}} \quad (16.2)$$

However, for membrane applications, where the need to constrain physical dimensions and the mechanical properties required impose limits on the acceptable swelling ratio, Equation 16.1 can be used to predict equilibrium polymer concentration and swelling ratio for a gel with a known cross-link density. Figure 16.10 shows such a prediction for a dextran-based gel with an initial polymer fraction of 0.16 based on a dextran of 500 kDa. Other parameter values are given in Table 16.2.

### 16.4.1.2 Charged Gels

The equilibrium swelling theory assumes that the degree of swelling of a charged gel changes as ions diffuse in and out of the gel (Figure 16.11) [66]. Swelling results from the effects of three forces. In addition to the dynamic effects of mixing and elastic constraints seen with uncharged gels, an additional force will result from the charge effects within the gel [23]. This leads to expressions that also take account of the effects of both pH and ionic strength on gel swelling.

**FIGURE 16.10** Effect of increasing molecular weight between cross-links on swelling ratio and equilibrium polymer fraction of a neutral hydrogel. Simulations conducted for a dextran-based gel using the parameter values in Table 16.2.

#### Anionic gel

$$\frac{V_1}{4l} \left( \frac{v_{2,s}^2}{\bar{v}} \right) \left( \frac{K_a}{10^{-\text{pH}} + K_a} \right)^2 = [\ln(1 - v_{2,s}) + v_{2,s} + x_1 v_{2,s}^2] \left( \frac{V_1}{v\bar{M}_c} \right) \left( 1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) v_{2,r} \left[ \left( \frac{v_{2,s}}{v_{2,r}} \right)^{1/3} - 0.5 \left( \frac{v_{2,s}}{v_{2,r}} \right) \right] \quad (16.3)$$

#### Cationic gel

$$\frac{V_1}{4l} \left( \frac{v_{2,s}^2}{\bar{v}} \right) \left( \frac{K_b}{10^{\text{pH}-14} + K_b} \right)^2 = [\ln(1 - v_{2,s}) + v_{2,s} + x_1 v_{2,s}^2] \left( \frac{V_1}{v\bar{M}_c} \right) \left( 1 - \frac{2\bar{M}_c}{\bar{M}_n} \right) v_{2,r} \left[ \left( \frac{v_{2,s}}{v_{2,r}} \right)^{1/3} - 0.5 \left( \frac{v_{2,s}}{v_{2,r}} \right) \right] \quad (16.4)$$

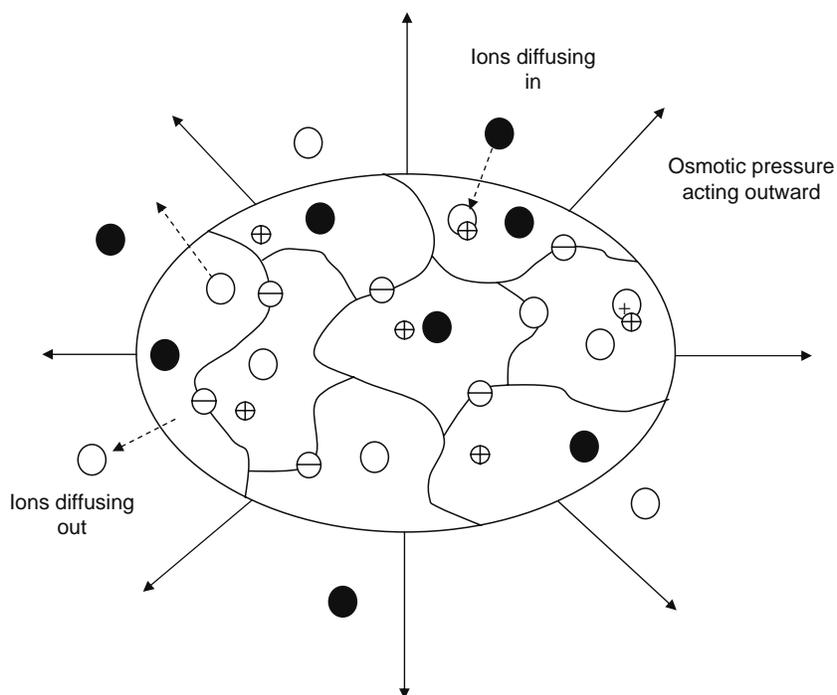

where

$l$  is the ionic strength

$K_a$  and  $K_b$  are dissociation constants for acid and base, respectively

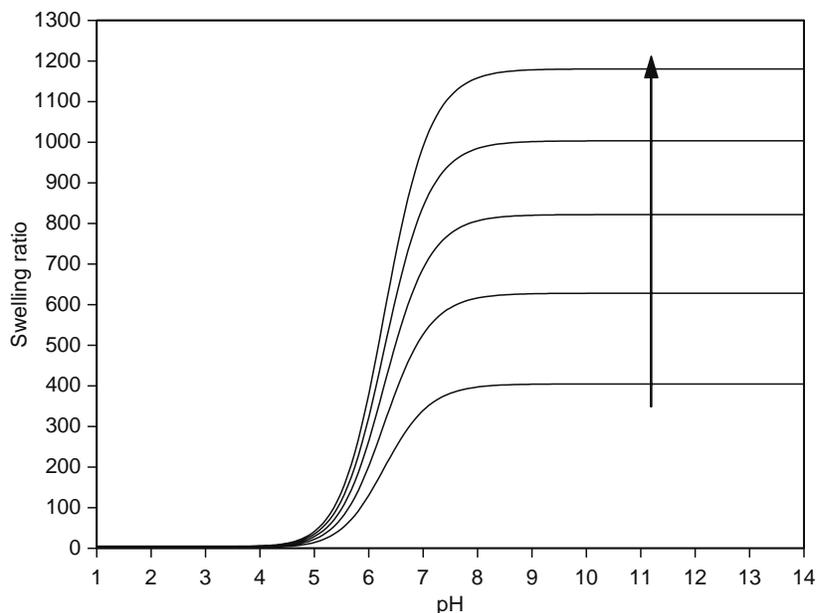

**TABLE 16.2**  
Parameter Values Used for Simulations (Polymer is Dextran)

Parameter	Definition	Value	Dimensions
$C_n$	Flory characteristic ratio	3.3	—
$fb$	Force per bond	$1.2 \times 10^{-7}$	N
$x_1$	Flory polymer-solvent interaction parameter	0.473	—
$\gamma$	Bond interaction distance	$5 \times 10^{-12}$	m
$v_1$	Partial specific volume of the polymer	0.62	$\text{cm}^3 \text{g}^{-1}$
$D_1$	Diffusate diffusivity in the liquid phase	$1.1 \times 10^{-10}$	$\text{m}^2 \text{s}^{-1}$
$K_c$	Dissociation constant for competitor/ligand	$1 \times 10^{-3}$	M
$V_1$	Molar volume of water	18	$\text{cm}^3 \text{g}^{-1}$
$l$	The unit length along the polymer back bone	$5 \times 10^{-10}$	m
$r$	Hydrodynamic radius of the solute	$1.5 \times 10^{-9}$	m
$v_{2,r}$	Polymer fraction of the gel after gel formation	0.04	—
$\bar{M}_n$	Number average molecular weight of the polymer	$4.8 \times 10^5$	$\text{g mol}^{-1}$
$M_r$	Molecular weight of the monomer (glucose)	180	$\text{g mol}^{-1}$
$K_D$	Dissociation constant for receptor/ligand	$1 \times 10^{-3}$	M

**FIGURE 16.11** Phenomena affecting the swelling of a charged hydrogel in a buffered pH solution. (Redrawn from De, S.K., Aluru, N.R., Johnson, B., Crone, W.C., Beebe, D.J., and Moore, J., *J. Microelectromech. Syst.*, 11, 544, 2002.)

In responsive applications based on these gels the cross-link density does not change, but the gel will swell in response to changes in ionic strength or pH. Figure 16.12 shows simulation results obtained using Equation 16.3 to determine the effect of pH on the equilibrium polymer volume and hence the swelling ratios for a CM-dextran gel. Comparison of the swelling ratios predicted for neutral and charged dextran gels in Figures 16.10 and 16.12 suggests that pH-sensitive gels show much higher swelling ratios even at high cross-link densities. In a range of simulations of swelling effects in carboxylated polyacrylates,

**FIGURE 16.12** Simulation of the effect of pH on the swelling ratio for a carboxymethyl dextran gel. The arrow indicates increasing chain length between cross-links (simulation conditions given in Table 16.2, ionic strength 30 mM).

Brannon Peppas and Peppas [23] found swelling ratios up to 250 for systems where the swelling solution had an ion concentration comparable to the charged groups in the gel. For a preswollen gel, changes in swelling ratio can be computed from  $\nu_{2,s}$  values obtained at appropriate pH values.

These relationships are commonly employed to determine  $\bar{M}_c$  in characterization studies of nonresponsive and responsive hydrogel preparations where the response does not lead to a change in cross-link density.

### 16.4.1.3 Affinity Cross-Linked Gels

In the case of affinity gels, where the response is based on a change in the cross-link density, the effective value of  $\bar{M}_c$  will depend on both covalent and reversible cross-links based on bio-specific or affinity interactions. Here the  $\bar{M}_c$  value resulting from covalent links alone can be determined using Equations 16.1 and 16.2 under conditions where the reversible cross-links are all open, i.e., saturating competitor concentration. Then the effect of a change in competitor concentration ( $C$ ) on the number of affinity cross-links can be predicted together with its effect on gel swelling.

In hydrogel containing fixed concentrations of immobilized ligand and receptor  $L_{\text{tot}}$  and  $R_{\text{tot}}$ , respectively, the mass balance for receptor ( $R$ ) sites within a finite mass of gel can be written as [67]

$$[R_{\text{tot}}] = [R] + [RL] + [RC] \quad (16.5)$$

Assuming mutual depletion of receptor ( $R$ ) and ligand ( $L$ ) populations, but that the competitor ( $C$ ) reservoir is sufficiently large that competitor concentration is unchanged by binding, gives an expression for the dissociation constant for ligand binding:

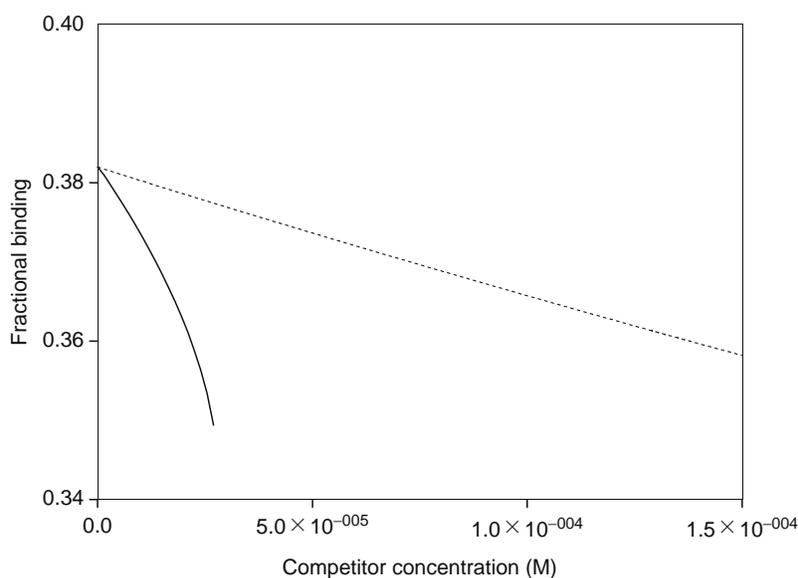

$$K_L = \frac{([R_{\text{tot}}] - [RL] - [RC])([L_{\text{tot}}] - [RL])}{[RL]} \quad (16.6)$$

The dissociation constant for competitor binding is

$$K_C = \frac{([R_{\text{tot}}] - [RL] - [RC])[C]}{[RC]} \quad (16.7)$$

where  $K_L$  and  $K_C$  are the dissociation constants for the immobilized ligand and competitor interactions, respectively.

Equations 16.6 and 16.7 can be combined to give a quadratic expression in  $[RL]$  which can be used to determine the fraction of receptor, which is bound to immobilized ligand (Figure 16.13). From these equations, the number average molecular weight ( $\bar{M}_c$ ) between affinity cross-links can be determined:

**FIGURE 16.13** Effect of competitor concentration on fractional binding of immobilized receptor to immobilized ligand in a responsive hydrogel. Broken line denotes solution for fixed volume. Solid line accounts for dilution effect of swelling. Both ligand and receptor concentrations 1 mM, other values as per Table 16.2.

$$\overline{M}_c^{\text{aff}} = \frac{[P]\overline{M}_n}{[R_{\text{tot}}]Y} \quad (16.8)$$

where

$[P]$  is the polymer concentration in the gel

$Y$  is the fraction of immobilized ligand bound to receptor ( $[RL]/[R_{\text{tot}}]$ )

The polymer fraction of the gel  $\nu_{2,r}$  after gel formation can be determined from the mixture conditions, as the polymer and total mass of the mixture is known. The effect of changing competitor concentrations can then be expressed in terms of the effect on  $\nu_{2,s}$ . In the case of an affinity response the swelling ratio (sr) of a preswollen gel can be computed from changes in the  $\nu_{2,s}$  resulting from a change in competitor concentration.

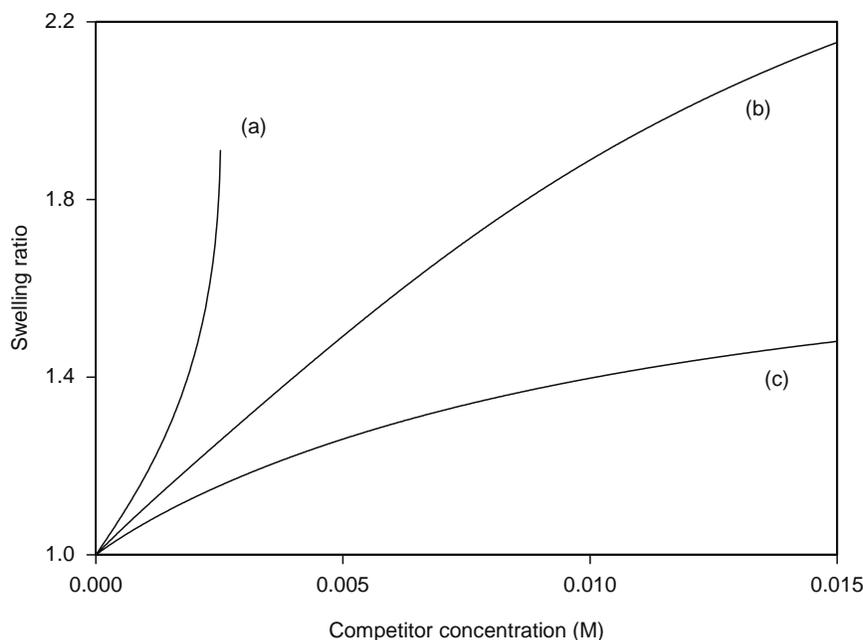

$$\text{sr} = \frac{\nu_{2,s}^1}{\nu_{2,s}^2} \quad (16.9)$$

In a chemically cross-linked responsive gel containing both bio-specific or affinity interactions and covalent cross-links at a specified density, the cross-links determining the swelling ratio will represent the sum of both covalent and affinity links ( $\overline{M}_c + \overline{M}_c^{\text{aff}}$ ).

In Equations 16.5 through 16.7,  $R_{\text{tot}}$  and  $L_{\text{tot}}$  are defined relative to the initial gel volume. Therefore, after swelling, these concentrations will be reduced as follows:

$$R_{\text{tot}}^s = \frac{R_{\text{tot}}}{\text{sr}} \quad \text{and} \quad L_{\text{tot}}^s = \frac{L_{\text{tot}}}{\text{sr}} \quad (16.10)$$

This requires iterative solution of Equations 16.2 and 16.5 through 16.10, as changes in ligand and receptor concentrations will change swelling ratio, which will in turn change concentration. Simulations using this approach show that as a soluble competitor for the affinity interaction is introduced, the number of cross-links is reduced and the gel swells (Figure 16.14). In the case of a gel with no covalent cross-links the solution fails when the number of links per polymer chain falls below two, i.e., the minimum theoretical number needed for gel formation.

**FIGURE 16.14** Effect of competitor concentration on the swelling of a gel in equilibrium with a solvent at zero competitor concentration.  $R_{\text{tot}}$  and  $L_{\text{tot}}$  5 mM, dissociation constants 1 mM for both ligand and competitor. (a) Zero covalent cross-links per chain—gel/sol transition occurs, (b) 5 covalent cross-links per chain, and (c) 10 cross-links per chain.

### 16.4.2 PREDICTION OF MESH SIZE

Increasing the swelling ratio will have two effects on a gel:

1. For a gel sheet of constrained surface area, the thickness will increase.
2. Mesh size of the gel will increase.

When the gel used as a gating membrane to control the release of solute these will have two competing effects on flux:

1. Increases in mesh size will increase the gel diffusivity tending to increase transmembrane flux.
2. Increases in swelling ratio will increase the membrane thickness tending to decrease transmembrane flux.

The effect of competitor on the thickness of a gel sheet ( $\delta$ ) will be given by

$$\delta^C = sr \delta \quad (16.11)$$

where

$\delta$  denotes membrane thickness

$\delta^C$  denotes membrane thickness in the presence of competitor

The influence of the mesh size will be seen in terms of its effect on diffusivity. Mesh size values for neutral gels have been calculated using the following expression [68]:

$$\xi = v_{2,s}^{-1/3} \left( \frac{C_n \bar{M}_c}{M_r} \right)^{1/2} l \quad (16.12)$$

where

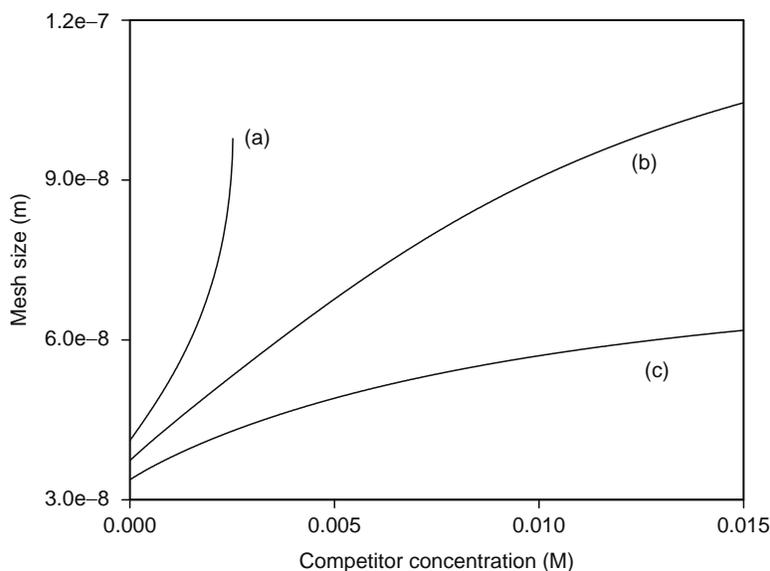

$\xi$  is the gel mesh size

$C_n$  is the Flory characteristic ratio

$l$  is the unit length along the polymer back bone

$M_r$  is the the molecular weight of the repeat unit

Figure 16.15 shows the predicted effect of competitor concentration on mesh size for the conditions reported in Figure 16.14.

**FIGURE 16.15** Effect of competitor concentration on mesh size, simulation conditions as for Figure 16.14.

### 16.4.3 EFFECT OF SWELLING ON BINDING CONSTANTS

An additional effect, which may be important in affinity gels with high degrees of swelling, is the effect of tensile stress on binding constants. Gel swelling results in a force being applied to the cross-links within the gel [65]. In affinity cross-links, this would be expected to increase the dissociation rate constant. This effect is encountered in studies of affinity-mediated cell-surface interactions and has been described by Bell [69] in terms of the applied force and bond interaction distance.

$$k'_r = k_r \exp\left(\frac{\gamma fb}{k_b T}\right) \quad (16.13)$$

where

- $\gamma$  is the bond interaction distance
- $fb$  is the force acting on the bond
- $k_b$  is the Boltzmann constant

For an apparent dissociation constant expressed as the ratio of reverse to forward rate constants,

$$K'_L = \frac{k'_r}{k'_f} = K_L \exp\left(\frac{\gamma fb}{k_b T}\right) \quad (16.14)$$

These effects can also be incorporated into the iterative prediction swelling but are likely to only be significant at high swelling ratios.

### 16.4.4 PREDICTION OF GEL PHASE DIFFUSIVITY AND PERFORMANCE OF RESPONSIVE MEMBRANES

The ability of a solute to diffuse within a hydrogel has been described in terms of the probability of a solute of characteristic size ( $r$ , defined as the radius of a sphere of equal volume to the solute molecule) passing through an opening equal to the mesh size of the gel ( $\xi$ ). This probability is taken to be a linear function of the ratio of  $r/\xi$ . Therefore, the gel phase diffusivity of a solute can be related to its liquid phase diffusivity, molecular volume, and gel mesh size [70,71].

$$D_{\text{gel}} \cong D_1 \left(1 - \frac{r}{\xi}\right) \exp\left(\frac{-1}{Q-1}\right) \quad (16.15)$$

where

- $D_1$  and  $D_{\text{gel}}$  are liquid and gel phase diffusivities of the solute, respectively
- $r$  is the hydrodynamic radius of the solute

Equation 16.15 shows that, as expected, the gel phase diffusivity approaches zero as the solute radius approaches the mesh size. In a responsive gel, as swelling increases in response to environmental changes gel phase diffusivity increases with increasing mesh size. Figure 16.16 shows the effect of competitor concentration on predicted gel phase diffusivity assuming a solute radius of 1.5 nm. Using this example and a dextran polymer gel, it is not possible to achieve a cross-link density sufficient to give a predicted mesh size sufficiently small to prevent gel phase diffusivity. However, as Equation 16.12 does not consider the steric effects of the immobilized receptor experimentally determined gel phase diffusivities are likely to be lower.

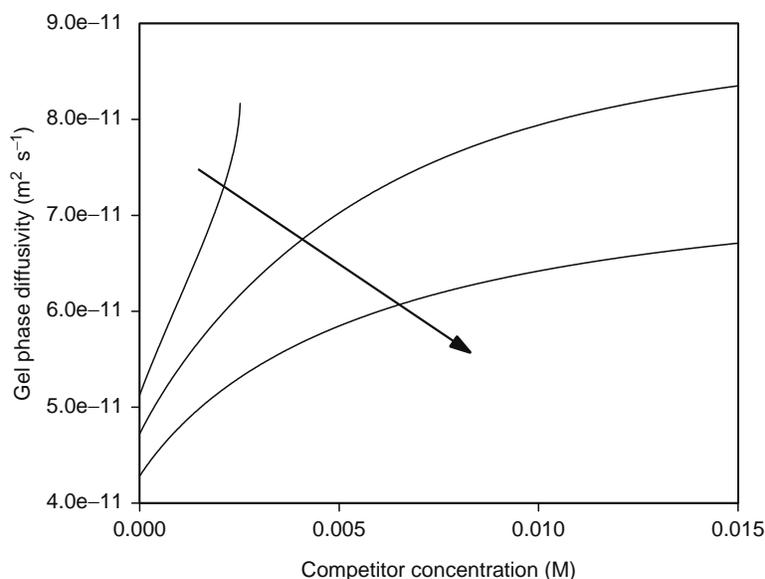

The final step in describing membrane performance is to consider the competing effects of competitor on diffusivity and membrane thickness. Using Fick's first law to describe transport across a thin slab of gel (a membrane)

$$J = \frac{AD_{\text{gel}}}{V\delta^2 C} (C_D - C_R) \quad (16.16)$$

where

- $J$  is the flux (concentration change per unit time)
- $A$  is the membrane area
- $V$  is the volume of receiving compartment
- $C_D$  is the donor compartment concentration
- $C_R$  is the receiving compartment concentration

Simulations of the effect of competitor concentration using Equations 16.11, 16.12, 16.15, and 16.16 are shown in Figure 16.17. This indicates that at low covalent cross-link density where swelling effects are more pronounced, flux passes through a

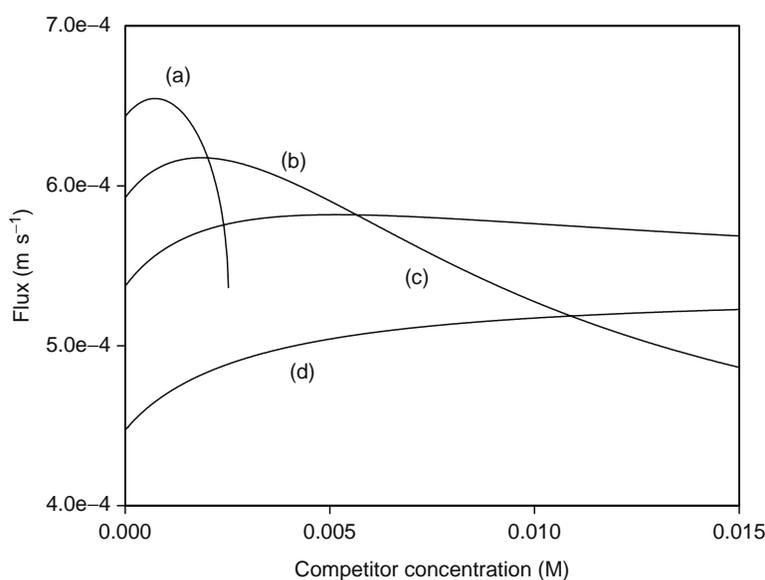

**FIGURE 16.16** Effect of competitor concentration on gel phase diffusivity. Arrow denotes increasing covalent cross-link density from 0 to 10 bonds per chain.

maximum as competitor concentration is increased. Gels which contain a higher covalent cross-link density show less swelling, and flux, although lower across the range, does not decrease at higher competitor concentrations.

#### 16.4.5 DESIGN IMPLICATIONS OF GEL PERFORMANCE
